UNILATERAL AND BILATERAL CARCINOMA OF THE BREAST*
(Including Paget's Disease)

Results Three, Five, Ten, Fifteen And Twenty Years After Operation

STUART W. HARRINGTON, M.D.

Rochester, Minnesota

CANCER of the breast is one of the most easily diagnosable forms of malignant tumor and it is probable that no form of cancer receives more surgical attention with such excellent results when treated by early primary radical operation. In spite of the fact, however, that countless patients, who otherwise would have died, have been operated on for cancer of the breast with excellent results, the general mortality from the disease has constantly increased, which indicates that there is an actual and not an apparent increase in the incidence of the disease.

The most important consideration in the treatment of cancer of the breast is early recognition of the disease and its immediate radical surgical treatment. There are no pathognomonic signs or symptoms by which all mammary malignant growths can be recognized. This, unfortunately, is particularly true of early lesions, and it emphasizes the importance of considering every lesion of the breast as being potentially malignant because delay in treatment may result in death from metastasis.

The educational program which members of the medical profession have for many years participated in, has been of great benefit in that a greater number of patients are seeking medical advice for lesions of the breast earlier in the course of the disease. This increases the responsibility of the physician, for lesions of the breast are seen before the characteristic signs of malignancy are present and it is often difficult to distinguish benign from malignant lesions on the basis of clinical signs and symptoms. In those cases in which carcinoma is suspected and in which the diagnosis is definite, the subsequent course and planning of treatment should be carried out by one who is thoroughly familiar with the management of such lesions of the breast. The initial treatment is by far the most important procedure and the possibility of cure often depends on its effectiveness.

I have recently made another complete study of the cases of all patients with carcinoma of the breast who have been operated on at The Mayo Clinic from 1910 to 1933, inclusive. In an effort to make this study as accurate as possible, I have again reviewed the cases from a pathologic standpoint, and in a few cases in which the pathologic classification was not definite, additional microscopic studies were made which in some instances have changed the classification. There were relatively few of these cases; however, the figures which I have previously published have not been materially changed.

This present study comprises 4,628 cases in which patients were operated on in the period from 1910 to 1933 inclusive. The results have been tabulated in terms of "percentage survival rates" after operation, that is, the percentage of patients who were living, three, five, ten, fifteen and twenty years after operation. The five-year "percentage survival rate" is what is

*From the Division of Surgery, The Mayo Clinic, Rochester, Minnesota. Read before the annual meeting of the Minnesota State Medical Association, Saint Paul, Minnesota, May 4, 1937.

sometimes referred to in surgical parlance as a "five-year cure." A word about the way in which the calculations were made is in order: Patients who were treated for the requisite number of years prior to the time of inquiry, which was as of January 1, 1937, were first selected for the three-year survival rate, patients treated in 1933 or earlier for the five-year rate, patients treated in 1928 or earlier, for the ten-year rate, and so forth. Obviously, therefore, the three-year rate was calculated on the basis of a larger number of patients than the five-year rate, and the five-year rate was calculated on a larger number of patients than the ten-year rate, and so forth. Of the patients who were operated on, any patient who was traced for an insufficient number of years was considered to be "untraced" and was therefore excluded from the calculation. For instance in calculating the five-year survival rate, a patient who had been operated on five years prior to the time of the inquiry but who was traced only for four years after operation and who was living at that time was considered as "untraced," for one cannot know whether that patient did or did not survive until the fifth year after the operation. For the purposes of calculating the three-year survival rate that patient *is* traced, however, for we do know that the patient survived more than three years after operation.

An exhaustive effort was made to trace all patients. When patients were delinquent in answering routine follow-up letters, local health departments, vital statistics bureaus, and so forth, were consulted to learn whether there was any record of death. In the end, only a small number of the patients remained untraced, 97 per cent of the patients who were operated on five or more years before the investigation having been traced for a period of five years or more. It is to be noted that hospital deaths are not subtracted from the traced group, so that hospital deaths are counted as are other deaths in the first year after operation. In the 4,628 cases in which patients were operated on, which constitutes the total group dealt with in this paper, there were thirty-eight hospital deaths, or a rate of 0.8 per cent. In this paper, therefore, I shall report the three, five, ten, fifteen and twenty-year results in cases in which patients were operated on for unilateral carcinoma of the breast and bilateral carcinoma of the breast, as well as the three, five, ten, fifteen and twenty-year results according to the grade of the malignancy in cases of unilateral carcinoma of the breast and the results of radical amputation for Paget's disease.

That malignant disease is not confined to any definite period of life is evidenced by the age incidence in this series. The youngest patient was seventeen, the oldest eighty-six years of age. In Table I is shown the age distribution of the patients for the entire series and also for those with and those without glandular involvement.

The results of operation depend on four important factors: (1) the extent of the disease at the time of operation, (2) the thoroughness with which the operation is performed, (3) the degree of the malignancy as measured by its list of pathologic grade at the time of operation, and (4) the age of the patient. Statistical studies are often misleading and may fail to give the true conception of the results obtained if proper attention is not paid to the specific character of the material dealt with. In studying carcinoma of the breast the first important consideration is the extent of the disease at the time of operation, and therefore the results will depend considerably on where the line is drawn between operable and inoperable conditions. I believe that this is one of the most inportant factors to be kept in mind in evaluating the results of statistical studies because, if only the small lesions without demonstrable axillary metastasis are considered surgical, the results would be unrepresentatively favorable. This method, however, would include only a relatively small number of patients, for the majority of patients present fairly well advanced lesions at the time of the initial examination. But even in this larger group of cases, in which there are more extensive lesions with ulceration and axillary metastasis, comfort and additional life can be given by proper surgical treatment and the patients deserve the benefit of this treatment.

There are varied opinions as to what constitutes operability. I will state briefly the criteria of operability which have been followed in this series of cases: Any lesion of the breast was considered to be operable if it was freely movable from the thoracic wall regardless of ulceration. In some cases even if there were cutane-

ous nodules proximal to the tumor, regardless of the presence or absence of palpable axillary lymph nodes, the lesion was considered operable. The same view of operability was held in most cases in which supraclavicular nodes were palpable but were confined to one side. In addition, patients were accepted for operation if they had a diffuse type of malignant growth, if malignancy was associated with lactation and, in most cases, if malignancy was associated with pregnancy. Those conditions were considered to be inoperable in which a large growth was fixed to the thoracic wall and there was very extensive metastasis to the regional lymph nodes or distant metastasis to other parts of the body. A few patients with distant metastasis were accepted for operation because of exceptional circumstances.

As those indicated, it is difficult to draw any sharp line between operable and inoperable lesions, and in each case treatment must be according to the findings. I have accepted for operation all patients to whom, I felt, there was a reasonable chance of offering comfort or greater length of life as well as those whose disease, I felt, there was a reasonable chance of curing. It may seem that these rules of operability have not been drawn strictly enough and that I am accepting for operation cases in which the growth is too extensive. This is a matter of opinion, however, and justification has been found in many cases in which the condition was thought to be absolutely hopeless before operation, but in which the patients have lived and enjoyed many years of comfort afterward.

I have ascertained for each year from 1910 through 1933 the percentage of cases in which there was lymphatic involvement at the time of operation. This percentage for the entire series was 64.0 and it has shown little variation in the last ten years of this period. In 1933, however, the percentage was 55.7. This relatively low percentage is very encouraging as it is the next to the lowest for cases presenting glandular involvement that have been seen since 1910, the lowest being 54.3 in that year. However, it is

only the sixth time that the percentage has been in the fifties. Our experience at the clinic during this period indicates that the medical profession's educational program is hopeful of bearing results, although this percentage of 55.7 is still too high and indicates that we are seeing patients too late in the course of the disease to expect the best results from surgical treatment. Table II shows how much better the results are in cases in which patients are operated on before glandular invasion has occurred and again strongly emphasizes the importance of early operation. As has been pointed out in Table I, more than half the cases (64 per cent) presented evidence of glandular metastasis at the time of operation. It will be noted in Table II that the percentage of patients who were traced, and who were living three or more years after operation, is nearly twice as great for the group without axillary metastasis at the time of operation as for the group with axillary metastasis; for patients who were living five years after operation the percentage was about two and a half times greater; for patients who were living ten years after operation, three and a half times greater; for patients who were living fifteen years after operation, four times greater, and for patients who were living twenty years after operation four and a half times greater for those who did not have axillary metastasis at the time of operation than for those who did.

A comparison was made of the results of primary as opposed to secondary operations, and the results for unilateral carcinoma are given in Table III. Those operations were considered secondary in which there had previously been a primary minor operation, elsewhere, for the same condition, and they comprised 11.2 per cent of all the operations for unilateral carcinoma. As Table III shows, the results for primary operations as indicated by the percentage survivals for the different years are better for the primary group than they are for the secondary group.

A study was also made to determine the results of amputation for unilateral carcinoma of the breast according to the grade of malignancy (Broders). This grading is based on the presence of cell differentiation, the greater the tendency of the cells to differentiate or to approach the normal, the lower being the grade of the malignancy. Lesions are graded on a basis of 1 to 4, grade 1 being the least and grade 4 the most malignant. A study was first made as to the relative frequency of each of the four grades of malignancy in cases of unilateral carcinoma. Not all the lesions in these cases were graded; 3,368, which comprised 77.1 per cent of the lesions, were graded, and 1,003, or 22.9 per cent, were not graded. Table IV shows the distribution of the various grades of malignancy for the entire group and compares the percentages in cases with and without glandular involvement for the various grades of malignancy. It is to be noted in this table that the high grades of malignancy comprise the largest percentage of all

cases, and that glandular involvement is present relatively less frequently when the lesion is of the lower grades of malignancy than when it is of the high grades. Thus for lesions of grade 1, only 7.8 per cent showed glandular involvement, whereas for lesions of grade 4, 88.3 per cent showed glandular involvement.

The grade of the malignancy is probably the most important indication as to the prognosis. This is again made more significant when considered in connection with glandular invasion. As has been previously shown, the higher the degree of malignancy the greater the percentage of cases with glandular involvement. The fact that the lesions in most of the cases I am dealing with were of a high grade of malignancy accounts for the high percentage of cases with glandular involvement, as these high grade lesions metastasize early to the regional lymph nodes. This again emphasizes the importance of early operation. The best results are therefore obtained in the case of lesions of lower degrees of malignancy without glandular involvement. The least satisfactory results are obtained in cases of grade 4 lesions with glandular involvement, and this holds true for the various years of survival after operation (Table V).

The results of the surgical treatment of bilateral carcinoma of the breast are shown for two groups: (1) those cases in which the carcinoma occurred in both breasts at the same time, designated as "simultaneous" carcinoma of the breast, and (2) those in which the carcinoma occurred in the second breast at a later time. The results for bilateral simultaneous carcinoma, which comprise forty-seven cases or 1.0 per cent of all cases of carcinoma of the breast, are, as would be expected, much less satisfactory than for those cases in which the carcinoma occurred in the breasts at different times. There were 210 of these latter cases, or 4.5 per cent of the total cases of carcinoma of the breast. The results in this latter group are better than would be expected, although it must be taken into consideration that these are the most favorable cases in the group, as many patients who later had carcinoma in the remaining breast had distant metastasis, which contraindicates any radical procedure on the remaining breast (Table VI).

Of all the cases of carcinoma of the breast in this series, only thirty-four patients, or 0.7 per cent, were classified as having Paget's disease. Like other forms of carcinoma, Paget's disease comes into existence by differentiation of epithe-

lial cells which appear to be practically limited in origin to protective or closely allied epithelium. It seems reasonable to classify Paget's disease with the squamous cell or epidermoid type of carcinoma. These cases are often associated with a ductal type of adenocarcinoma in the underlying mammary tissue. There is some difference of opinion pathologically as to whether malignancy originates in the epithelial structures or in the glandular structures in these cases; from a surgical standpoint, however, I believe that these patients should receive the same surgical treatment as those with adenocarcinomas. As will be shown in Table VII a relatively high percentage of these cases show glandular invasion, the percentage being 32.4. This is only half as great as that for all cases of carcinoma of the breast with glandular invasion, which was shown in a previous table to be 64.0 per cent. This proves very definitely that the lesions in these cases metastasize to the regional lymph nodes, necessitating a thorough radical procedure. As shown in Table VII, the results of radical amputation in cases of Paget's disease presenting glandular invasion are less satisfactory than in similar cases of the entire group of adenocarcinomas of the breast (Table II). In cases without glandular metastasis the results are more satisfactory for the three and five-year periods and not as satisfactory for the ten and fifteen-year periods.

Summary and Conclusions

A review has been made of all cases of carcinoma of the breast encountered at the clinic from 1910 to 1933, inclusive. Of the total of 4,628 patients, 97.4 per cent have been traced three years or more and the results of operation have been determined for three, five, ten, fifteen and twenty-year periods in cases of unilateral carcinoma of the breast, bilateral carcinoma of the breast, and Paget's disease (Tables I to VII inclusive).

The best surgical results were obtained in cases in which metastasis to the lymph nodes had not taken place. In this series of 4,628 cases, 1,676 cases (36.2 per cent) did not present axillary metastasis at the time of operation. It was found that 82.1 per cent of these patients were living three years, 72.1 per cent were living five years, 53.8 per cent were living ten years, 42.4 per cent were living fifteen years and 32.6 per cent were living twenty years or more after operation. In cases in which there had been lymphatic involvement, the results were less satisfactory. There were 2,952 cases in this group, or 63.8 per cent of the total; 41.9 per cent of these patients were living three years, 28.0 per cent were living five years, 15.6 per cent were living ten years, 10.0 per cent were living fifteen years and 7.4 per cent were living twenty years after operation.

As is shown by this study, the important indications as to prognosis following surgical treatment are the extent of the malignancy at the time of operation, particularly as to the presence or absence of axillary metastasis, and the degree of the malignancy, as shown by the miscropic examination of the primary malignant lesion.

NEW AUTOMOBILES AND NEW FRACTURES*

HARRY B. MACEY, M.D.

Rochester, Minnesota

TURRET tops, all steel bodies and shatterproof glass have not compensated for fast driving, reckless driving and driving while drunk. This is attested by the 36,000 deaths from automobile accidents in 1936 and by the recent enactment in Minnesota of a law prohibiting speeds in excess of sixty miles an hour in the daytime or in excess of fifty miles an hour after dark.

By the title of this paper, I do not mean to suggest that the fractures now incurred in automobile accidents are unheard of. It is true, however, that, in comparison with former days, physicians are seeing more uncommon and more multiple fractures.

TABLE I. PATIENTS, FRACTURES AND TYPES OF ACCIDENTS

Patients	100
Fractures	164
Patients in overturn accidents	42
Patients in impact accidents	43
Patients in impact and overturn accidents	3
Type of accident unknown	12
Patients who had multiple fractures, 33 per cent	

The frame of the older type of automobile was chiefly of wood. There was very little steel support and the outcome of severe accidents was practically demolition of the car. Its parts were scattered, its doors were unhinged and, not infrequently, motors were driven into the front seat. As for the passengers, frequently they suffered compound fractures, together with laceration of soft tissue.

Today soft tissue is better preserved, but the feature of present day accidents which makes their human products more difficult to handle is the fact that the multiplicity of fractures, which previously has been mentioned, leaves the patient in a state of more or less profound shock. The energy concealed in increased velocity has got to be absorbed somewhere.

Statistical Study

A statistical study of 100 consecutive cases, exclusive of those in which the skull was fractured, was made in an effort to give a cross section of the bones fractured and of the types of fractures sustained. The study is best reviewed from the point of view of the types of accidents (Table I). Automobile accidents in general entail either impact, defined as striking together, or overturning. Impact accidents (Fig. 1, *above*) result from head-on collisions or from striking bridge abutments, trees or any object which stops or impedes progress. Overturn accidents (Fig. 1, *below*) commonly occur secondary to cars being sideswiped or forced off the road by inconsiderate drivers. Blowouts and falling asleep while driving are less frequent causes.

Fig. 1. Destruction of automobiles *(above)* in impact type of accident, and *(below)* in overturn type of accident.

Thirty-three per cent of the individuals sustained multiple fractures; 100 patients sustained 164 fractures. Impact and overturn accidents occurred in about the same frequency. In our geographical district, with its long distances and high speed highways, a preponderance of over-

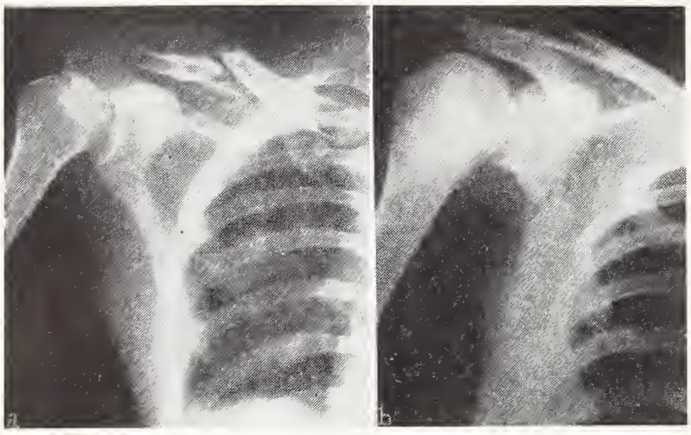

Fig. 2. Fractures commonly sustained in overturn types of accidents. *a*, Fracture of clavicle and scapula; *b*, fracture of scapula (the line across the surgical neck of the humerus is the epiphysis).

Fig. 3. Vertebral fracture commonly sustained in overturn type of accident.

turn accidents would be expected, whereas in large cities and more densely populated areas the impact type of accident would be expected to prevail.

As to bones injured, fractures of the ribs occurred in the highest proportion, 28.9 per cent (Table II). However, this high percentage is misleading in that only 17 per cent of the patients had fractures of the ribs: The high percentage is accounted for by the fact that usually several ribs were fractured. Twenty-four per cent of the individuals had vertebral fractures. These represented 20.2 per cent of the total number of fractures. The fact that a high percentage of fractures occurred about the upper extremity and shoulder girdle, was attributable chiefly to the large number of clavicular and scapular fractures. Clavicular fractures were sustained commonly whether the accident was of the impact or of the overturn type. As compared with the upper extremity and shoulder girdle, the lower extremity and pelvic girdle suffered less. The sternum usually is thought of as an unusual situation for fracture to occur; yet the sternums of 3 per cent of the individuals were fractured.

TABLE II. STRUCTURES FRACTURED

Structure	Per Cent
Vertebrae and processes	20.2
Ribs	28.9
Upper extremity and shoulder girdle	26.8
Lower extremity and pelvic girdle	22.3
Sternum	1.8
Total	100

Carrying the statistical study further, and reviewing the fractures in relation to the type of accident, several definite facts were brought out.

Overturn Accidents

Following overturn accidents, the frequency of fractures of the shoulder girdle (Fig. 2, *a* and *b*) and vertebral column (Fig. 3) was outstanding; 48.5 per cent of the fractures (representing 54.8 per cent of the patients) were of one of these structures (Table III). There was a tendency for these fractures to occur in combination, indicating that in this type of accident there is a common mechanism in their production. In the production of vertebral fractures of the compression type, and this is the type found after automobile fractures, force must be applied to the spinal column while it is in a flexed or jack-knife position; therefore, it would be logical to assume that, as the occupants are seated in a flexed posture, force is applied back and forth from the top of the car to the seat, as the car rolls over and over. This may further explain the situation of the fracture. Cervical fractures are produced by force applied from the top of the car to the skull, with the cervical portion of the spinal column flexed. In the pro-

duction of fractures of the thoracic and lumbar portions of the spinal column, direct force probably is applied to the shoulders, with the spinal column in a flexed, sitting position, or possibly the force is applied to the head, with the cervical portion of the spinal column in a neutral position. As the car continues to roll, the spinal column may assume different flexed positions and, with the reapplication of force, fractures may be produced at different levels.

In the production of clavicular fractures, indirect force is the most likely factor; probably, as the occupants are tossed from side to side, force is transmitted to the clavicle through the shoulder. These fractures are chiefly of the middle and outer third of the clavicle. Fractures of the outer third probably occur as a result of force applied to the shoulder in a slightly downward plane; fractures of the middle third probably result from force transmitted through the shoulder in a horizontal, or in a slightly upward, plane.

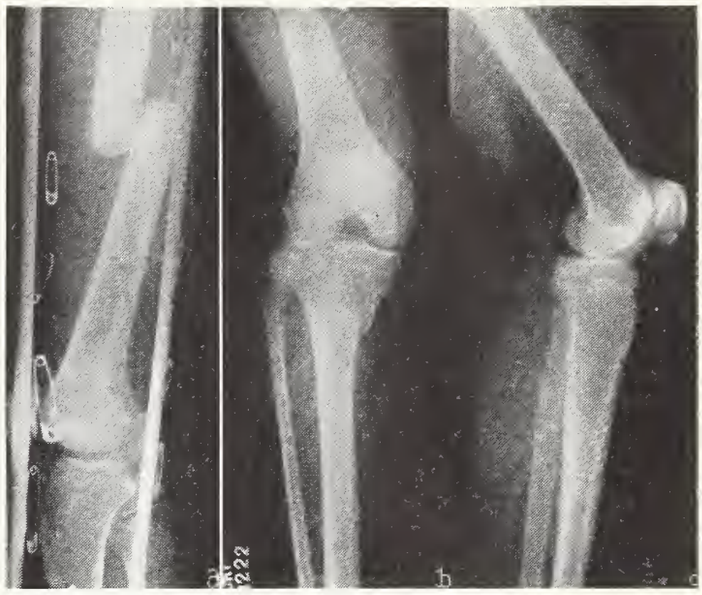

Fig. 4. Fractures commonly sustained in impact types of accidents. *a*, Fracture of shaft of femur; *b*, intra-articular fracture of knee; *c*, fracture of patella.

The mechanism of the scapular fractures that occur in this type of accident is difficult to explain; however, I assume that force is applied directly to the body of the scapula rather than indirectly to the glenoid. This assumption seems reasonable because scapular fractures in this series involved chiefly the body of the scapula rather than the processes or glenoid.

Impact Accidents

In the impact accident, in contradistinction to the overturn accident, there was an outstanding occurence of fractures of the lower extremities (Fig. 4, *a*, *b* and *c*). Forty-three per cent of the fractures (representing 46.5 per cent of the patients) were of the lower extremity and pelvic girdle. In Table IV, certain fractures of the lower extremity are mentioned; other fractures were of the leg, tarsus, hip, and ankle.

In many instances the position of the individual in the car could be learned. All of the patellar fractures, and 75 per cent of the fractures of the femoral shaft, affected occupants of the front seat. The patellar fractures probably result from striking the dashboard and the fractures of the femur result either from direct force transmitted from the dashboard to the

shaft of the femur or from indirect force exerted on the patella, with or without associated muscular action. An individual riding in the front seat probably would be aware of an impending accident and there would result a protective muscular reaction in which the feet would be pressed against the floor board and the muscles of the leg and thigh would be rendered tense. With the impact, the individual is thrown forward in accordance with the force of the impact. Thus it is conceivable that if the occupant is thrown forward, in a semi-crouching position, direct force on the knee, plus the powerful muscular action, could snap the femur. If the individual is thrown forward with the legs outstretched, direct force exerted by the lower margin of the dash may produce a fracture of the femur. The driver may sustain fractures of the femoral shaft from force exerted directly against the steering wheel.

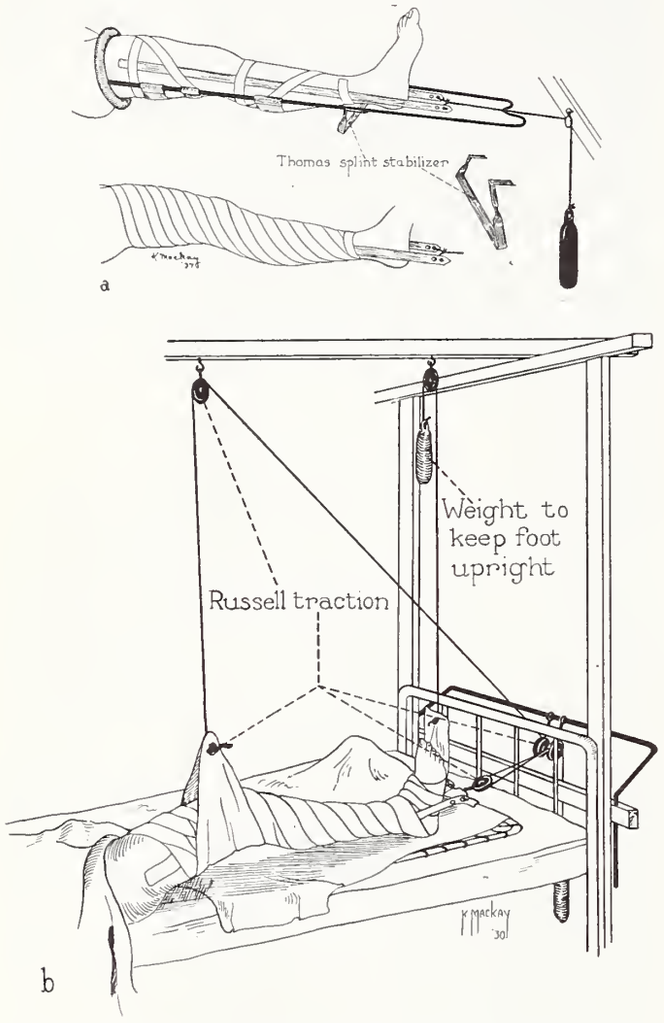

Fig. 5. Skin traction applied by means of adhesive tape and *a*, the Thomas splint; *b*, Russell method.

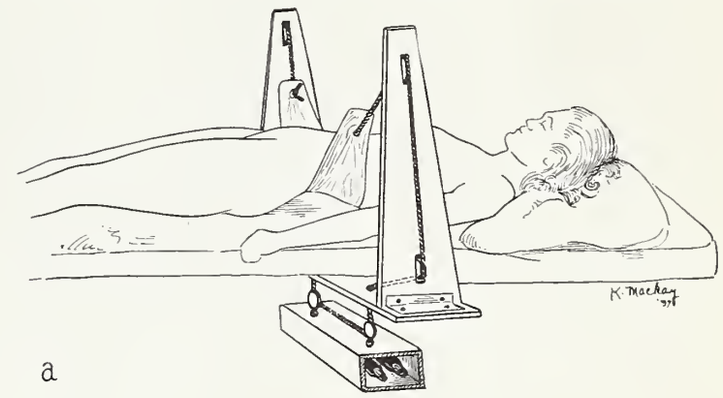
The percentage of vertebral fractures sustained in impact accidents was about half that sustained in overturn accidents. A large majority of fractures of the vertebræ in impact accidents probably result from the spine being snapped forward into flexion at the time of the impact. The percentage of fractures of the shoulder girdle and vertebræ sustained in overturn accidents also was only about half that sustained in impact accidents. Fractures of the shoulder girdle and upper extremities in the impact type of accident probably result from instinctive thrusting forward of the hand as a protective mechanism in bracing for the impact, with consequent direct or indirect exertion of force.

Treatment

In discussing the treatment of automobile fractures my remarks will be confined chiefly to the immediate care of these fractures. Not infrequently the patients are in poor general condition and treatment cannot be elective. Therefore, means of treatment or of protection of the fracture must be limited to those which will not make worse the general condition of the patient.

The Thomas splint, simple of construction and easy of application, is one of the most useful devices. It is made for use on the lower extremity but occasionally it can be successfully used in the immediate care of fractures of the upper extremity. The fixation and supporting functions of the Thomas splint often are employed in conjunction with skeletal or skin traction.

Skeletal traction can be facilitated by employment of the Kirschner wire. The wire can be inserted at the bedside, under local anesthesia. The sites of election for introduction of the wire are through the femoral condyles or tibial tubercle. By means of this wire, adequate traction can be instituted early, commonly as an emergency measure and, frequently, as an elective measure in cases of fracture of the femur. In the same manner, fractures of the leg can be treated by applying the traction to the calcaneus or to the lower third of the tibia just proximal to the ankle joint. Should the general condition of the patient permit an elective course of management, traction by Kirschner wire offers an excellent method of treatment of fractures that are compounded or associated with badly traumatized surrounding soft tissue.



Skin traction can be applied by use of adhesive

tape or moleskin, and is efficient for short periods with heavy traction, or for longer periods with light traction. It is well used in certain instances. The Thomas splint also can be used in the immediate care of fractures about the hip (Fig. 5, *a*).

A third method of skin traction, reported by Russell, can be applied without detriment to the patient's general condition (Fig. 5, *b*). This has been found to be effective in treating fractures about the tibial tuberosities of adults and fractures of the femoral shaft of children. It is most effectively used on children if applied bilaterally for unilateral fractures of the femoral shaft.

Fractures of the patella usually require open operation. This is particularly true of fractures of the patella acquired in automobile accidents, because of their comminuted nature. Emergency measures consist of splinting, and possibly of aspiration of the hemarthrosis. Surgical treatment, as employed today for fracture of the patella, consists of internal fixation. In one method of fixation that is widely used, fascia lata is passed through the fragments, or encircles the fragments, and is sutured in position; in another, a rustless steel wire is introduced anteriorly and encircles the fragments of the patella. In its insertion the wire loop is passed through the quadriceps, patellar tendon and lateral capsular expanse, or if preferred, may be passed through the bony fragments, thereby insuring stability. Should fascia lata be employed as a means of fixation it is advisable to repair the usually associated lateral tear in the expanse of the capsule, using either chromic catgut or strips of fascia lata.

Hyperextension, the treatment for compression fractures of the vertebral bodies, is best maintained by well fitting plaster-of-paris casts. The danger of injuring the spinal cord by hyperextension should be kept in mind, and the method should not be applied until roentgenograms have made it evident that this danger does not exist. Frequently the condition of the patient necessitates delaying the application of plaster-of-paris casts, in which case hyperextension should be instituted in some simple and convenient manner. In cases of fracture of the lower thoracic and lumbar portions of the spinal column, hyperextension can be attained by means of rolled blankets, suspension slings (Fig. 6, *a* and *b*) or ingeniously devised frames. In cases of cervical fracture and in cases of fracture of the upper part of the thoracic portion of the column, traction by some type of head sling,

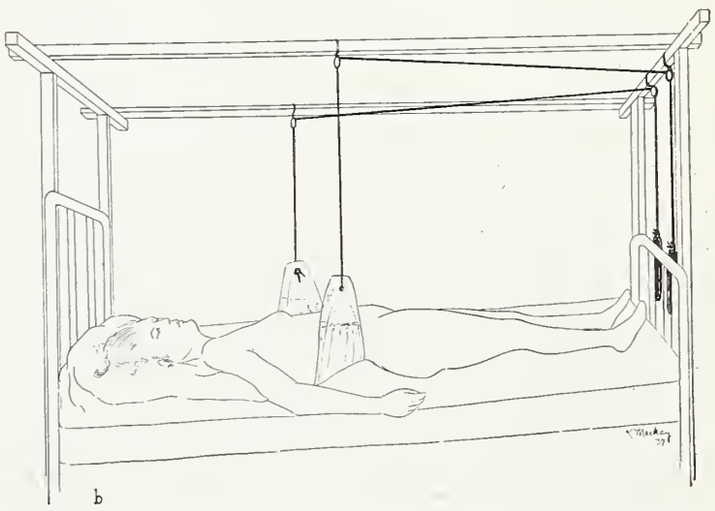


Fig. 6. *a*, and *b*, Different types of suspension sling for use in vertebral and pelvic fractures.

with or without hyperextension, can be instituted easily.

In considering vertebral fractures, I would urge that all complaints referable to the back, particularly a complaint of persistent soreness, be thoroughly investigated roentgenologically. Soreness, often mistaken for that of muscular contusion, may be the result of a fracture which can be revealed only by roentgenologic examination. I would urge that lateral roentgenograms always be included in the examination, for frequently a vertebra which appears normal in the anteroposterior roentgenogram will be found to be the site of a compression fracture when viewed laterally.

Fractures of the ribs, although painful, rarely are difficult to treat and simple immobilization for several weeks usually suffices.

Fractures of the shoulder girdle, so common in the overturn type of accident, usually can be

treated by elective measures from the beginning. In a rare case, surgical measures may be resorted to from the beginning. The clavicle most commonly is fractured in its middle third; less frequently in its outer third. In this series of

Fig. 7. Abduction humerus splint in treatment of clavicular fracture.

cases, none of the fractures were of the inner third. Treatment of fracture of the outer, or of the middle, third is directed toward correction of the deformity. This deformity usually consists in separation of the fragments, with the outer fragment carried downward by the weight of the upper extremity and the proximal fragment pulled upward by the sternocleidomastoid muscle. Correction is attained by elevation and extension of the shoulder. If manipulative reduction is employed for the simpler type of fracture, fixation is best afforded by a combined Sayre and Velpeau dressing. If delayed reduction is employed, and the fracture is simple, treatment can be carried out by the clavicular T splint, by clavicular rings, or by some type of special splint or some form of traction. If the fracture is comminuted, delayed reduction is indicated. Manipulative procedures are rarely employed. A device which we, at the clinic, have found particularly effective for treatment of both simple and comminuted fractures of the clavicle is the abduction humerus splint, made in such a manner that the arm is held abducted about 110° and in slight extension (Fig. 7).

In scapular fractures, it is the body of the bone which usually is broken. Fortunately, the scapula is so placed that it is well protected posteriorly by muscles and anteriorly by the thoracic wall. Because of this, simple immobilization of the associated upper extremity for a period of two to three weeks usually suffices.

In this series, none of the sternal fractures required other than simple strapping by means of adhesive tape applied across the anterior thoracic wall. However, should gross displacement take place, open operation and reduction often will be required.

Comment

In closing, I would like to emphasize that in this review of 100 cases there occurred three sternal fractures and ten scapular fractures, fractures heretofore considered rare. Several textbooks either omit discussion of these fractures or give them slight mention. Furthermore, I would like to call attention to the fact that multiple fractures now are common results of automobile accidents. The overturn type of accident commonly produced fractures of the vertebra and shoulder girdle, whereas the impact type of accident commonly produced fractures of the lower extremities. Skull fractures, most commonly the cause of death in automobile accidents, have purposely been omitted in this discussion.

PERIPHERAL NERVE INJURIES*

ARTHUR A. ZIEROLD, M.D.

Minneapolis, Minnesota

INJURIES to the peripheral nerves, while not of frequent occurrence, are of importance by reason of the prolonged and many times permanent disability which accompanies them. The end-results following treatment are probably not the best possible. This is true not because nerve injuries pass unrecognized or because the possibilities of treatment are not known but because most of us have no definite plan of procedure. Only too often we are confronted with permanent disabilities that might have been avoided had the patient been aware of what he might

*Presented before the annual meeting of the Minnesota State Medical Association, Saint Paul, Minnesota, May 5, 1937.

reasonably expect from treatment and, what is of prime importance, when that treatment should be undertaken. This paper will discuss briefly the development of a reasonable plan of treatment that will best conserve the factors necessary for success.

Nerve injuries in themselves are relatively simple in their nature but are often complicated by association with other injuries to tendons, muscles, vessels, and bones. A primary nerve injury may consist in nothing more than a concussion. This is manifested by a loss of function without structural damage. Next in order of severity is contusion of the nerve wherein there is actual cell damage and often interstitial hemorrhage. Last and most severe of the primary injuries is partial or complete section of the nerve trunk. Classed as secondary injuries are those compressions of the nerve resulting from the development of scar within the nerve trunk which frequently follows contusion or the external scar which results from lacerations of the surrounding tissue. Included in this and differing only in the character of the tissue is the compression of the nerve trunk by bone fragments or callus.

While symptoms of nerve injuries may by careful study be elaborated into a very complex syndrome, they may also be reduced to simple terms. When a nerve is injured there is a partial or complete loss of motor power or sensation or both. These are the primary signs of nerve damage and the areas affected can usually be identified with the affected nerve without a great deal of difficulty. Most prolonged study is undertaken in the attempt not to identify which nerve is injured but rather the nature and extent of the injury and its progression. If definite organic nerve injuries occur, secondary symptoms and signs will develop in the course of time. Vasomotor disturbances giving rise to changes in color and temperature develop so early as to be almost primary symptoms. The unopposed muscles give rise to deformities and finally, as atrophy and fibrosis of the muscles develop, these deformities become permanent. In the latest stages the involved joints become fixed by reason of muscle contracture or shrinkage of the capsule. Together with the muscular atrophy, atrophy of the skin frequently occurs and, with this, changes in nail structure and hair distribution. In some instances, particularly in the lower extremities, ulceration may occur. These signs and symptoms are the gross outward evidence of nerve injury and may all or in part disappear with regeneration of the nerve. The manner of this may perhaps be best understood by a brief consideration of the histopathology.

What we class as peripheral nerves are those spinal nerve trunks consisting of sensory fibers from the posterior spinal roots and motor fibers from the anterior roots together with fibers communicating with the sympathetic ganglia. These are united in cable-like strands surrounded by a fibrous tissue sheath and subdivided by fibrous tissue septa. There are few if any purely motor or sensory nerves if we exclude the cranial nerves, although in some one element may predominate almost to the exclusion of the other. Although in our consideration of nerve injuries we are dealing with nerve trunks made up of numerous smaller fiber bundles, these fibers are all projections of cell bodies within the central nervous system or the sympathetic ganglia. Therefore, the changes which occur in peripheral nerve injuries must be considered in terms of a single cell. For example, an anterior horn cell of the spinal cord sends out its neuraxis which transverses the spinal nerve uninterruptedly to the muscle to which it is joined by specific end plates. This neuraxis is made up of numerous protoplasmic fibrils and is surrounded by myelin and the tubular sheath of Schwann. When section of the neuraxis occurs, degeneration promptly begins. This consists of fragmentation of the neuraxis fibrils and final decomposition attended by proliferation of neurilemma cells until the end-result is a tubular sheath filled with an undifferentiated, nucleated strand of protoplasm. This occurs almost simultaneously throughout the length of the distal fragments and is complete within two weeks. This state of affairs may persist unchanged for several months. As time progresses, however, the tubular sheath contracts until finally the degenerated distal fragment of nerve is represented by nothing more than a fibrous tissue strand with a few inclusions of protoplasm. As the distal fragment of nerve degenerates, the central stump also degenerates for a distance of two or three millimeters. Following this, however, regeneration of the nerve begins. The fine fibrils of the neuraxis proliferate and grow distally with rounded bulb-like ends, into the exudate at

the site of the injury. If uninterrupted by scar or undue separation of the fragments they pass into the previously mentioned neuraxis tube of degenerated nerve substance and grow in a rather regular manner toward the periphery. Because a sensory fibril may grow into a motor ending and vice versa, the mathematical chances of perfect anatomical regeneration are slight, but because of the great number of fibrils the chance of functional results is good, once the site of injury has been passed. It might be supposed that a nerve trunk with its included fibers laid down in a regular arrangement would not regenerate successfully after section unless each fiber tract had opportunity to grow into its proper and corresponding tube in the distal fragment. Because of the many intra-neural communications and plexuses this is found not to be necessary. It is, of course, obvious that the more nearly a nerve approaches an unmixed type the more satisfactory will be the end-result and the less will be the misfit of nerves and nerve endings.

If, however, a nerve be sectioned and the fragments separated, allowing scar tissue to intervene, the outgrowing fibrils in the central stump will turn upon themselves and form a loose network together with the newly formed scar, giving rise to a bulb-like stump which is the neuroma commonly found at operation. If this condition is allowed to persist for many months the distal degenerated portion of the nerve gradually contracts until the pathway for regenerating fibrils is lost. If instead of section the nerve has sustained a contusion with injury to nerve tissue the distal part may degenerate and regeneration from the proximal stump may take place uninterruptedly and successfully. On the other hand, if the contusion is severe, sufficient scar tissue may develop within the nerve to cause pressure enough to kill the newly growing fibrils and regeneration not only stops but what has previously grown following the initial injury is often lost. This process is duplicated in cases in which the nerve is compressed by bone or callus or other extraneous scar. Although the continuity of the nerve may be intact, function is lost by the injury of compression.

From this brief pathology, I believe, may be gathered the manner in which peripheral nerves are injured and the mechanism of their regeneration. The next step is to make this information useful. The patient wants to know what can be done about his injury: what can be done to aid and insure recovery of nerve function.

The first and least formidable procedure is neurolysis. The injured nerve is exposed and freed from scar tissue or bone and relieved of compression. In so doing, continuity is not interrupted and fibril pathways are restored. If the nerve has been bruised and internal scar has formed in such manner as to block pathways or compress regenerating fibrils, relief may be obtained by the forcible injection of saline or even incision of the fibrous sheath and instrumental separation of the fibers. This procedure, of course, can rarely be used in old injuries. If the nerve has been sectioned or too much obstructing scar within or surrounding the nerve has been formed, resection and anastomosis of the nerve trunk may be performed. This is the most difficult and is only employed when other means fail. If the resected segment of nerve is too great to allow anastomosis, a transplant of nerve from other portions of the body may be required.

The next consideration in order is a plan of procedure. When shall we operate upon the nerve injury and what operation shall we employ? If a peripheral nerve has been seriously injured and there is a question whether or not regeneration will take place, the site of injury should be explored immediately. Although this is at times less simple than it sounds, it can be done carefully and the nerve exposed without injury. If, at the site of injury, there is no interruption of continuity, the nerve should be protected with fat or other material and the surrounding tissue carefully replaced. The patient should be regularly observed and deformities and contractures avoided by adequate splinting and massage. If at the end of six to eight months no signs of regeneration appear, the nerve should again be explored and the area of injury or scar excised and anastomosis performed.

If immediate exploration reveals a section of the nerve, anastomosis should be performed at once. In this way, prompt exploration discloses any actual nerve section sufficiently early to prevent secondary complications such as muscle and joint change or atrophy, and sufficiently

early to afford the best opportunity for complete nerve regeneration. If, on exploration, the continuity of the nerve is found to be intact, no damage is done by the exploration and conservative measures can be employed. On the other hand, if exploration is delayed several months awaiting regeneration (and, to be logical, this period should be at least six months) many operable cases will be unnecessarily handicapped, regeneration will be less prompt and sure, and many secondary complications will be developed which otherwise might have been avoided. Furthermore, the status of the nerve which does not require immediate suture will not be improved.

If confronted with a fresh wound and exploration reveals section of a nerve, the nerve should be united by suture even in the face of possible infection. There is everything to gain and nothing to lose. If the wound heals without pus formation, regeneration is well on its way with a minimum of scar and the best possible chance of success. If, on the contrary, the wound suppurates, the nerve ends are in better position than if allowed to separate and become imbedded in the resultant scar tissue. When sepsis subsides and the wound has healed, resuture of the nerve is usually necessary but this cannot be done immediately. An infected wound should not be reopened within a six-months period. At the end of this time successful regeneration is still quite possible and the chances of a clean field are reasonably good.

Summary

From the foregoing plan of procedure what may be reasonably expected?

1. Roughly, 50 per cent of all injuries to the peripheral nerves recover function without operation.

2. Of the uncomplicated cases which require neurolysis or nerve suture, 75 per cent may expect functional recovery.

3. Of those cases which require nerve transplant, the percentage of success is considerably less.

4. Following nerve suture, the first evidence of regeneration seldom appears before four months and may be delayed two or three months longer.

5. Improvement may be expected for twenty-four to thirty months.

6. The results from primary suture are much better than the results from secondary or delayed suture: recovery is more often complete and the time of regeneration shortened and the secondary complications are obviated.

7. Of the various nerves subject to operation it is probable that one regenerates about as rapidly and as successfully as the other although from the published figures almost anything may be proven. It is probable, however, that the nearer a nerve approaches a pure type, either sensory or motor, the better are the chances of regeneration.

THE TREATMENT OF BURNS*

ROBERT F. McGANDY, M.D.

Minneapolis, Minnesota

ANY consideration of burns, like other injuries, from an industrial viewpoint should have the following objectives:

1. Prevention.
2. Lowering of the mortality rate.
3. Returning the patient to employment in the shortest possible healing period and with a minimum of permanent disability.

As a matter of fact there is no difference between these objectives from an industrial viewpoint than from that of private practice.

Ninety per cent of all burns are due to carelessness. Industry attempts to prevent burns as well as other accidents by:

1. Rigid physical examination of all applicants for employment.
2. Reëxamination of all employees at stated intervals and following illnesses.
3. The activity of safety crews and safety appliances.

A similar campaign might be carried on for the prevention of so-called non-industrial burns. This might be done by impressing the lay people, particularly women, with the hazard of their

*Presented before the annual meeting of the Minnesota State Medical Association, St. Paul, May 5, 1937.

clothing. Special precaution should be taken in protecting children in the preschool age.

Outside of industry, women are burned more frequently then men. The mortality rate in hospital cases in the past ten to twelve years has been reduced to one-half. It is significant, however, that 45 per cent of all deaths due to burns are in children between one and five years.

Historically, there is nothing new in the treatment of burns. At the present time, and for many years past we have been employing methods which were in vogue at one time or another, over many centuries, and which have been recently reintroduced and exploited. The treatment of burns really started with man's discovery of fire. Salves, ointments and oils have been used for ages, and their value can be attributed to the fact that anything covering a burn allayed pain. Hippocrates, in 430 B. C., used a combination of oil and resin in the treatment of burns. Alum and other astringents were used in the sixth century, A. D. The use of limewater and oil, which was the forerunner of carron oil, was recorded in the third century, B. C. Tait used paraffin in 1864 but it did not become popular until 1915. Picric acid was first used in 1864. Open air treatment was recorded as early as 1867. Water baths were used in 1858. Lister used boric acid compresses for burns exclusively and it is possible that he had the present popular infection theory for the toxemia of burns in mind at that time. The Chinese, in the sixth century, B. C., used a strong infusion of tea as wet dressings. One might say that one of the earliest treatments recently has become one of the most modern treatments. In general, one might say that burns have passed through periods of fads and fancy without much real investigation, until the last twelve years.

The various agents producing burns are too numerous and familiar to everyone to enumerate here. I am going to limit this paper to the consideration of superficial burns and scalds in general, rather than to those due to specific agents, as electricity, et cetera. Burns vary in extent and degree, depending primarily on the agent producing the burn. The American classification of burns into three degrees is the one most generally used, and I am sure all of you are familiar with it. I feel that Berkow's method of estimation of the extensiveness of surface burns showing the percentage ratio of parts burned to the total body surface, is of great value. One must remember, however, that burns, regardless of their extent, are more serious in some localities than in others. This is especially true in burns about the genitals, neck and orifices. Briefly, the prognosis of burns depends on the burning agent; sex, age, and occupation of the burned patient; depth and extent of the region involved, as well as the physical condition of the patient at the time of the burn.

The general course of extensive superficial burns, and by this I mean burns involving 15 to 20 per cent of the body surface, can be divided into the following stages:

1. Initial shock.
2. Secondary shock.
3. Toxemia or sepsis.
4. Healing.

Initial shock, when present, begins immediately and is coincident with the occurrence of the burn. It is now thought that it is due to an upset of the vasomotor mechanism caused by afferent nerve impulses from the injured area. It is characterized by an anxious expression on the face and a moist grey skin. The temperature may drop slightly while the respirations become elevated and shallow. Blood pressure as a rule falls, but as the systolic and diastolic pressure usually fall together, there is little if any change in pulse pressure. This stage passes off as a rule with heat, opiates, et cetera.

Secondary shock usually follows in two to ten hours. There have been numerous theories advanced for this stage. The theory accepted now by most authorities is that of blood concentration. It is thought that the burn alters the permeability of the capillary walls. This, in turn, allows the escape of blood plasma from the body into the burned area. There is a definite measurable increase in blood viscosity. Blood concentration can be estimated by using a hemoglobinometer and this fact should be remembered, as it gives an easy method of determining the amount of fluid intake. As you know, a marked concentration of blood results in failure of circulation with an inefficient oxygen carrier. This means oxygen starvation of the tissues, resulting in falling of the temperature and finally death, if allowed to continue. One of the earliest signs of secondary shock is lowered pulse pressure, with or without a fall of the systolic pressure. A drop of less than 30 mm. in an adult, especial-

ly if the systolic is below 100, is definite evidence of early secondary shock. The pulse becomes rapid and, if at the same time it becomes feeble, it is an indication of advanced shock. The respirations become rapid as well. These in general are some of the common findings in secondary shock. As these conditions can be aggravated by exposure, coarse cleansing or scrubbing of the burned area, and the application of irritating antiseptics, et cetera, it is very obvious that one should forget the local burn and treat the patient systemically until the shock has safely passed or is under control.

In view of these facts, and others which I will take up later, I am sure you can readily see why I feel that lay people coming in contact with an extensive superficial burn should wrap the victim in a blanket or sheet, keep him warm and call a doctor or transport the patient to a hospital as soon as possible. Too often, some overwilling neighbor, employee or ambitious safety man pushes the poor victim deeper into shock by applying his or her favorite ointment, salve, paste, oil or other "household" remedy and then damages the patient further by showing the bystanders what a neat bandage he can apply. The real tragedy, however, is the fact that these applications must be removed by the doctor when the patient reaches him, so that the more necessary water-soluble escharotics can be applied. Fortunately the doctor can use nitrous oxide if the patient's condition does not permit otherwise. I cannot too strongly impress upon you my feeling that, from the standpoint of everybody concerned, the patient with extensive burns is best let alone, with the exception of course of wrapping him in a blanket or sheet and keeping him warm. A patient seen some some time after a burn has been received should be given opiates to relieve pain and prevent the further development of shock.

When the patient reaches the hospital, he should be placed in bed under a cradle where the temperature is kept at about 90 degrees. Fluids should next be started. These can be given intravenously, but, if the patient's condition warrants, any method may be used. It is generally accepted that saline and glucose be used in order to take care of the blood chlorides lost and to protect the liver. If the patient's temperature is subnormal, these fluids are best given at 105 to 110 degrees. Blood transfusion, except for sepsis, is best reserved for shock from trauma rather than burns. Many men recommend gum acacia in this stage as an initial measure and I heartily approve of it. A severe burn usually requires intravenous fluids for three days. A good rule for quantity is 1,000 c.c. per twenty-five pounds of body weight in twenty-four hours. A good adjuvant measure in the treatment of burns in this stage is the use of extract of suprarenal cortex. This is used in one c.c. doses and repeated at intervals. This extract, as in the case of Addison's disease, increases the efficiency of the circulatory mechanism and apparently checks some of the salt loss through the kidneys. So much for the control of fluid intake in combating blood concentration.

How may we now control fluid loss? It is definitely known that blood concentration and subcutaneous edema of the tissues following burns reaches its peak in twenty-four to thirty-six hours following injury. A hemoglobin determination may reach as high as 180. It has also been demonstrated that a third degree burn involving one-sixth of the body surface results in a fluid loss of 70 per cent of the total blood volume in twenty-four hours. This means that an adult weighing 65 kilograms having a blood volume of about 5,000 c.c. would lose 3,500 c.c. of fluid from the blood stream in twenty-four hours. Two out of three deaths in burns occurring in the first twenty-four hours, excluding of course those who die of primary shock and in those cases immediately hopeless, are attributed to the rapid concentration of blood and the great loss of blood plasma. So the ideal first dressing in extensive burns is one which not only allays pain by covering the burned surfaces but also, what is more important, prevents the loss of fluids from the blood stream. Too much credit cannot be given to Davidson, who, in 1925, called attention to the use of tannic acid in precipitating broken down burned tissue and thereby sealing off the capillary bed at the outset and preventing loss of body fluid. Time does not permit me to go into the details of this technic, and it is familiar to you. In review, may I state that most men now use tannic acid in a 10 per cent freshly prepared aqueous solution rather than the more dilute solution first advocated. There are many who use a 20 per cent solution, as coagulation takes place more rapidly with the stronger solution. This, however, does more damage to

the normal epithelial cells left in the burn, as I will explain later. Of the three methods of applying tannic acid, I believe the spray method far exceeds the other two. Immersion of the patient in a tub of tannic acid solution, although it can be done, requires a large amount of help and solution. Wet tannic acid dressings, like the objection to wet dressings in general, are painful to change because they adhere to the underlying structures and oftentimes reduce the patient's temperature and increase shock. The spray method is simple and can be carried out under a tent with ease or with the aid of a warm air blower or lamp in smaller areas, such as on the extremities. It is essential that the tannic acid result should be obtained as quickly as possible in order to retain body fluids. By the same token, tannic acid is of little value after fluid loss has reached its peak. For then, the reverse process takes place and fluid loss is not a factor. With the aid of heat and warm air, coagulation can be completed in six to twelve hours, and in eighteen hours at the outside. The use of silver nitrate with tannic acid is painful in extensive burns, and what is worse destroys unburned epithelial tissue which is invaluable for regeneration.

Picric acid in aqueous solution will coagulate tissue, but, due to its toxicity, I believe it should be limited, if used at all, to the ointment preparation for the emergency treatment of small burns and scalds. Alcohol, which is an excellent esclarotic, I reserve for the treatment of minor burns. Here I feel it is of considerable value.

At this point, I wish to call your attention to a new group of escharotics, namely, the dyes, but before discussing these, I am first going to briefly consider toxemia. For many years, we have heard about toxic substances originating at the site of burns, circulating through the blood stream, causing elevation of temperature and other symptoms. Robertson and Boyd, in 1923, published an article describing primary and secondary proteoses. Various articles enumerate, in all, about ten or twelve so-called toxic substances. Many feel the evidence in support of the theory of absorption of toxins from the burned area back into the body is indefinite and contradictory. There has never been a constant toxic agent described nor has there been any agreement as to the nature of the toxin or the manner in which it works. The best evidence seems to be based on clinical observation. Recently, Underhill and Kapsinow repeated the work of Robertson and Boyd, injecting an extract of burned skin into an animal and producing toxemia. By the same technic, however, they made an extract of normal skin and obtained the same results. On further analysis, they found the extract according to the original technic contained alcohol. As a control, therefore, they injected a like amount of alcohol into the experimental animal and got the same toxic results that they obtained from both the burned and normal skin. They concluded, therefore, that Robertson and Boyd's results were due to the alcohol. Underhill has injected whole blood from a burned patient into an animal and produced no toxicity. Harrison and Blalock grafted burned skin into a fresh wound on a normal dog and didn't produce toxemia. Later, Underhill, Hapsinow and Fisk injected methylene blue and another dye into burned animals and found the dyes rapidly went into the edema fluid but did not go back into the blood stream to any significant extent. They also injected five times the lethal dose of strychinine about the burned area and found no symptoms of poisoning in the animal. They concluded that, due to the change in capillary permeability, the body fluid shifted from within outward and that if methylene blue and strychnine could not get back into the body, how could some vague toxin be absorbed in sufficient quantity to account for the so-called toxemia of burns. Neither can we attribute toxemia to blood concentration. This is evidenced by the fact that fluids can be kept up to a normal level by watching the blood chlorides and hemoglobin, and yet symptoms of toxemia will appear.

It was in 1929 that Aldrich of Boston and Firor of Johns Hopkins University, because they were impressed by the fact that there was enough infection present in all large superficial burns to account for the symptoms of toxemia, began an investigation along this line. They were also impressed with the fact that practically no work had been done on the bacteriology of burns. They, therefore, took careful repeated cultures from burned areas and from the fluid under the blisters. In the first twelve hours, as a rule, they got no growth. After the first twelve hour period, it was found that in 100 per cent of patients severely burned and a large majority of those with minor burns, a growth of hemolytic streptococci

was found. The concentration of these organisms paralleled the increase in the signs of sepsis from the beginning of the toxic stage of the patient. At the end of forty-eight to fifty-six hours pure cultures were obtained and the organisms had outgrown all others. It is the opinion of Aldrich and Firor that a burn is a large open surgical lesion bathed in virulent pus. Moorhead has defined a burn as, "an infected wound due to heat." It is interesting that the general condition of an untreated burned patient has a course similar to many widespread hemolytic streptococcus infections. Additional evidence was obtained from blood cultures of patients after the toxic stage had started. These showed the same strain of streptococcus as was found on the burned surface. In fatal cases, cultures from the heart blood and lungs also revealed streptococcus hemolyticus. Davidson felt that tannic acid rendered the toxic substance in a burn non-absorbable, but Aldrich feels that the power of tannic acid lies in the formation of an eschar over a practically sterile burn and sealing of the burn, which prevents fluid loss and further contamination. Davidson also pointed out that the general condition of the patient depended on the condition of the eschar. The condition of the patient was good as long as the eschar remained dry. You have probably had the experience of having most large burns treated with tannic acid eventually become infected. These facts and the theory of infection caused Aldrich and Firor to look for a new escharotic which, at the same time, would prevent an infection. Such a substance, of course, would have to be non-toxic when used in large quantities for extensive burns. After considerable search they began to use gentian violet, which would not allow Gram-positive streptococci to grow even in the presence of proteins and could be used in large quantities. You, undoubtedly, have all used gentian violet in such infections as: impetigo, indolent ulcers, and certain ear conditions. The dye is not only an antiseptic, specific for streptococcus hemolyticus but also reacts with the superficial burned skin to form a light, tough, flexible eschar. The eschar is more apt to remain dry, and, what is more important, the patient is free from sepsis. Gentian violet is used the same as tannic acid, namely by the spray method. It can be applied every fifteen minutes to one-half hour and my experience with it has been very favorable. Aldrich later found that it had one weakness, namely, that it was not a specific against Gram-negative organisms, which enter burns secondarily. He then tried to find some one substance that would be highly antiseptic against both Gram-negatives and Gram-positives and would have the power of escharosis as well as being non-toxic when used for extensive burns. A search through the anilin dyes, as well as the azos and chloramids failed to reveal the answer. He therefore settled upon a mixture of gentian violet, brilliant green and neutral acriflavine as the answer to his problem. He uses gentian violet, three parts by weight; brilliant green two parts by weight; neutral acriflavine, one part by weight. Two grams of this mixture, commonly known as the Aldrich dye mixture, are dissolved in 100 c.c. of water and used in the same manner as gentian violet. Briefly, the patient is placed under a cradle and when shock is under control the local treatment is begun. Aldrich does not believe soap and water preparation is necessary with the dyes. Blisters are opened and loose shreds of epidermis are trimmed away. If ointments and oils were used before admission, these are removed by patting the burns gently with an ether sponge. Personally, I still use soap and water also, but heartily believe that if extensive debridement is necessary the patient should be put to sleep with nitrous oxide. The dye is then sprayed on and after it dries another coat is applied. This process is kept up until a good eschar is obtained. Pain usually disappears after the second application. Once the eschar is formed no further dye treatment is necessary unless the burn becomes secondarily infected. This is true, particularly in children where the eschar is torn off or in burns near the orifices. The eschar should be inspected every day, soft areas excised, and the dye reapplied rather than antiseptic solutions as in the case of similar situations with tannic acid. It should be kept in mind that softening of the eschar is not always due to infection in either the tannic acid or dye treatment. Necrosis from pressure and melting of fat from heat can also cause soft areas. It is the experience of all who have used the dye method that softening under the eschar due to infection is not nearly as frequent as in the case of tannic acid. In general, the advantages of the dyes over tannic acid is that the eschar with dyes is thin and pliable and is therefore more comfortable

and less liable to crack and allow secondary contamination. There is little if any antiseptic value in tannic acid, whereas the dyes are specific for the bacteria found in burns. This, in turn, lessens the number of pockets of infection so common in tannic acid treatment. It is a well established fact that tannic acid, although it will not affect normal skin with the cornified layer present, will kill the prickle cell and germinal layers if this layer is absent. This retards epithelization and increases the likelihood of the need for skin grafting. The dyes, on the other hand, do not kill any of the skin layers. For the same reason, the chance of scar formation is lessened. Both methods, however, have the common properties of saving lives by sealing off the capillary bed and thereby reducing shock, allaying pain, simplifying the care of extensive burns and reducing the number of dressings required.

For those who question the use of dyes alone, I find two methods of combining them with tannic acid being used. The burned surface is prepared as usual. In one method, the surface is first sprayed or painted with a 2 per cent aqueous solution of gentian violet. After drying, the tannic acid spray is used until an eschar is formed. The other method incorporates a 2 per cent aqueous solution of gentian violet in 10 per cent tannic acid. This solution is used as tannic acid or gentian violet alone. I have used both these methods more than the gentian violet alone or the newer so-called Aldrich mixture, which has only recently come to my attention. The only objection I find to the dyes is staining of the bed linen, but this is no worse than with mercurochrome and some of the other antiseptics we have all used.

Occasionally, an extensive burn comes to the surgeon which has been poorly treated or not treated at all and has survived the stages of shock. Infection is the paramount issue in these cases and it is best taken care of locally by clearing up the infection as rapidly as possible with saline or Dakin's compresses. In addition, it has occurred to me that if the toxic stage of burns is due to a streptococcus hemolytic infection, and I believe it is, the surgeon might treat cases with prontylin or any other brand of sulfanilamide. This is merely a suggestion as I haven't had much experience with the drug in this type of case and I can find no mention of it in the literature to date.

Concerning healing of extensive burns, there seem to be two procedures where escharotics are used. One method is to leave the eschar alone until it falls away, epithelization having been completed under it. The other method hastens this process by the early removal of the eschar and stimulation of granulation tissue and epithelization by other means. As granulation tissue is not ready for grafting for three or four weeks, I recommend the eschar be left alone until this time has passed, unless it comes away before. No harm is done in removing small areas of eschar for inspection purposes before this time, however. If one decides to go ahead, and each case is an individual one, the tannic acid eschar must be cut away, whereas the dye eschar can be easily loosened by saline compresses and then peeled off. In small areas a stimulating ointment can be used such as scarlet red alone or in combination with oxyquinolin. Epithelization can be promoted also, and I am personally impressed with thioglycerol for this purpose. In large burned areas grafting is eventually necessary, and I feel the sooner it is done, the better from the economic standpoint alone. Preparation of the area for grafting is a personal matter as a rule, but I feel Dakin's pack for twenty-four hours followed by saline packs is a very effective method. Here again, the method of grafting is a personal one with most surgeons and I will not go into it. Generally speaking, small full-thickness grafts seem to be the most popular.

The indications for skin grafting in burns are:

1. To cut down the size of the lesion.
2. To fill in areas when the burn has become indolent in its ability to spread epithelium.
3. To stimulate the spread of epithelium from the periphery of a burn.
4. To prevent contractures, especially over the flexor surfaces and where there are folds in crevices and motion.

In general, early skin grafting is indicated to cover with epithelium as much of the burned surface as possible and cut down the size of the burned area as soon as possible. Late skin grafting is used to complete epithelization where nature is slow, or to prevent disability from contractures.

There are a few general considerations in the treatment of extensively burned patients that I might mention in closing. The patient should be placed in the best position to prevent con-

tractures. This is especially true in burns about the neck, axilla and flexor surfaces of the extremities. Competent nursing care is very essential and the patient should be kept in the best mental attitude. Food should be adequate. Carbohydrates should be pushed where the metabolism is increased due to fever. All the vitamins are necessary and especially vitamin "C," if there is infection. Secondary anemia, which is common in extensive burns, should be watched for and taken care of by the administration of iron. Lastly, I wish to remind you that two-thirds of the body sulphur is in the skin. It is a clinical fact that patients on a high sulphur intake grow epithelium faster than those on a sulphur-deficient diet. This need is taken care of by adding two or three eggs to the daily diet.

CERTAIN DERANGEMENTS OF THE KNEE JOINT*

C. C. CHATTERTON, M.D., F.A.C.S.

Saint Paul, Minnesota

IN dealing with the subject it will be quite impossible to consider more than briefly injuries that take place in and around the knee joint. We must reflect on the anatomy and physiology of the knee joint, discuss the symptoms and treatment and briefly the methods of disability rating. Personally, I like very much to consider disabilities of the knee joint in two classes, based on the clinical history: (1) disabilities that are likely to cause locking of the knee joint; (2) disabilities that do not cause locking of the knee joint.

The anatomy and physiology of the knee joint.—The knee joint is more than a hinge joint. It is a so-called gliding joint because with its power of flexion of 135° it also has a rotary power of 45° to 60° and a lateral motion usually of about 5°.

Because of the great freedom of motion controlled principally by muscular and ligamentous restriction, the knee joint is not well adapted to stand stress and strain, especially rotary strain. In fact, rotation is not well controlled until the knee is in full extension, when the bony anatomy with the power of the quadriceps extensor holds the knee joint stable. Muscle control through the quadriceps extensor is the most important mechanism in maintaining stability of the knee joint, and muscle defense is the first buffer to stress and strain. After muscle defense is overcome, the ligaments and capsule next come into play, and extreme continuous force may stretch or tear the ligaments themselves or from their bony attachments, allowing extreme motion of the joint with resulting injury to the cartilage, the menisci, synovial lining, the fat pads, and the ligamenta alaria.

The lateral ligaments and capsule control lateral motion, except when the knee is in full extension. The crucial ligaments control the extreme anterior and posterior motion.

The semilunar cartilages by their shape tend

*Presented before the annual meeting of the Minnesota State Medical Association, Saint Paul, Minnesota, May 5, 1937.

to deepen the tibial tuberosities and make compensation through their slight motion for a better fit between the condyles of the femur and tibia, and it is believed that they also act as the spreaders of synovial lubrication and help prevent friction. The semilunar cartilages are maintained in position by the coronary ligament to which they are attached.

Abnormal Conditions Which May Produce Locking in the Knee Joint

1. Injury to the cartilages (menisci), external or internal.
2. Loose bodies or joint mice.
3. Slipping patella.
4. Damage to the fat pad.
5. Fracture of the tibial spine.

1. *Injuries to the Cartilage (external or internal meniscus).*—The type of injury may be a tear or split of a portion of the cartilage with or without tags: the entire cartilage may be dislocated into the intercondyloid notch, the so-called bucket handle type of injury; or the cartilage may be torn at the attachment of the coronary ligament, which may cause extreme freedom of motion to the cartilage so it can be displaced, causing locking of the knee joint without actual fracture or damage of the cartilage itself. The meniscus has no blood supply except at the junction with the coronary ligament, and actual repair of an injury to the meniscus proper usually does not take place.

The anterior portion of the meniscus is most subject to injury and most defects are found in the anterior half of the meniscus. It has been my experience that the internal cartilage is damaged in the ratio of approximately fifteen to one compared with the external cartilage.

The mechanism producing an injury to the cartilage is usually lateral strain or rotary strain or a combination of both, and along with any severe cartilage injury we frequently expect to find injury to the lateral ligaments.

The history of injury may be of severe trauma or the condition may occur after minor stress such as assuming a squatting position. The diagnosis of damage to the cartilage after one single injury is difficult, but after recovery from swelling and inflammation, and with a history of repeated catches and localized pain along the edge of the cartilage plus the so-called positive Jones test (pain on making pressure over the cartilage and extension of the knee), negative x-rays which exclude loose bodies, dislocated patella, surgical inspection of the knee joint is warranted. The external cartilage frequently gives, with other findings, a musical sound or click upon examination. Recently Steindler has found that auscultation of the joint may be of value in diagnosing internal derangements of the knee joint, especially those of the cartilage.

2. *Loose Bodies.*—Loose bodies found in joints are usually composed of bone and cartilage and are most frequently associated with two conditions: (1) osteochondritis dissecans, which is a separation of a small amount of bone and cartilage from the articular surface; and (2) osteochondromatosis or synovial enchondromatosa. Rarely a loose body may result from the breaking off of a hypertrophic spur in osteoarthritis or after a fracture of the joint surface, or from an organization of clots of fibrin forming rice bodies in the joint.

There are several theories as to the cause of *osteochondritis dissecans.* Many feel that, because of its usual location at the site of greatest stress and strain, trauma is the sole cause. Fat or bacterial embolism is thought by some to be a causative factor. Low grade arthritis or a variant of arthritis deformans is considered by others as a predisposing cause.[1]

The symptoms of trouble in the knee joint may be noted long before the actual separation of the loose body, which may take months or years, but after the body has become separated the spasmodic locking of the joint due to the mechanical interference of free motion in the joint is quite conclusive for diagnosis. In many cases it is possible by x-ray examination to discover the punched out area before the loose body has formed, and removal of the affected area at that time may prevent the formation of a number of bodies.

Osteochondromatosis is usually easily diagnosed by the roentgen ray because of the large number of loose bodies seen. Some are bone, some are cartilage, many are pediculated, many free and they usually pack the joint and mechanically block free motion of the joint and produce locking. The real cause of osteochondromatosis is unknown, but trauma and infection seem to be the likely causative agents.

3. *Slipping Patella.*—While external slipping of the patella cannot be classed as a true internal derangement of the knee joint, as this condition often produces a painful twinge and occasionally definite locking, I feel that the discussion here with conditions that produce similar symptoms is proper.

This condition is seen in children and women much more frequently than in men, and because cartilage injuries are rare in children, the diagnosis after careful analysis and description is usually quite easy. Slipping patella may be unilateral or bilateral and is usually associated with a mild knock-knee and in young individuals who have unusual freedom of joints. Something occurs in the knee that temporarily restricts the motion, is usually quite painful and at the same time it is noted that the patella has assumed a position on the outer side of the knee joint. There may be an instant of restriction of motion or the knee may remain locked until manipulation releases the patella. The accident is usually followed by a period of swelling and pain about the knee.

4. *Damage to Retropatellar Fat Pad.*—This condition is quite frequently seen in middle age. My experience is that the diagnosis of injury to the cartilage has been made and upon exposure of the joint the fat pad is found to be abnormal in shape, inflamed, thickened and in such position that it could easily interfere with the mechanical motion of the knee joint. It is indeed difficult to make a positive diagnosis of locking of the joint due to the fat pad until after exposure of the joint.

5. *Fracture of the Anterior Tibial Spine* or the anterior portion of the tibia may lock the knee joint and prevent extension. X-ray studies will at once show the bone block and demonstrate the pathological condition and the diagnosis in this injury is not usually difficult.

Disabilities That Do Not Cause Locking

1. Rupture of the lateral ligaments.
2. Rupture of the crucial ligaments.
3. Fracture of the patella.

1. *Rupture of the Lateral Ligaments.*—Severe sprains with minor symptoms about the knee joint are most common, but when either of the lateral ligaments has been severely damaged, the stability of the knee joint is greatly impaired. Rupture of the internal lateral ligament is caused by overadduction commonly seen in football accidents of line play, clipping and tackling in an open field. The external ligament is frequently injured by accidents producing overabduction.

Sprains of either ligaments are usually only partial tears, and, while there is marked limitation of motion perhaps to a small arc, absolute locking is rare and is usually produced by some internal derangement of the structures of the knee joint.

Swelling, edema, limited arc of motion, localized pain over the external or internal ligaments or their attachments with increased lateral motion are the usual signs and symptoms of ruptured lateral ligaments. It is difficult at the time of injury to evaluate the amount of injury or tear to the ligaments, but with continued abnormal lateral motion, enough to disable the patient, an attempt to repair the damaged part should be made.

2. *Rupture of the Crucial Ligaments.*—Damage to the crucial ligaments may be caused by a combination of the same force and mechanism that causes damage to the cartilages. Usually torsion is necessary along with hyperabduction and adduction, to rupture both crucial ligaments. Rupture of the anterior crucial ligament allows forward gliding of the tibia on the femur, and when the posterior ligament is ruptured the tibia can be pushed backward, and if both are backward. This condition causes a feeling of ruptured there is great instability of the tibia as it may easily be pushed well forward and insecurity or giving way of the knee joint, but true locking is absent. Tenderness is found over the spine of the tibia with injury to the anterior crucial ligament, and just below and to the inner side of the patella upon flexion when the posterior crucial is damaged. Usually in this condition the lateral ligaments also are damaged, giving the objective and subjective findings of a relaxed, unstable knee joint.

3. *Fracture of the Patella.*—Fracture of the patella, complete or partial, may cause marked instability to the knee joint. If the fracture is complete the loss of ability to extend the knee is present. True locking is not seen, but swelling and injury to the soft parts may materially

affect the range of motion. The diagnosis of fractured patella is usually easy with the roentgen ray. Usually there is pain on attempting extension of the knee joint, with the point of tenderness over the injured patella.

Treatment

The old dictum that the knee joint should be opened with caution still holds good. Infection after operation is a surgical catastrophe, usually resulting in ankylosis or perhaps an even more serious result. But we feel that the knee joint has resisting powers against infection greater than was formerly realized, and infection even after frequent opening of joints is relatively uncommon.

If, after an accident, diagnosis is not certain, it is much better to wait and treat symptomatically, giving the joint a chance to recover spontaneously. Then if symptoms return at least a tentative diagnosis can be made and operation considered.

The danger of an unstable joint which at any time may give way, causing the patient to fall, cannot in the city dweller or in any individual be lightly dismissed. Repeated injuries, with internal derangement to the joint, may also cause degenerative changes quite as damaging to the function of the joint as the original injury.

When operation is considered, I feel that the patient should present himself at the hospital at least twenty-four hours previous to the operation, and should have a normal white count, normal temperature, and be free from demonstrable infection. The leg, thigh and knee should be carefully clipped and painted with merthiolate or 3 per cent iodin, after a soap, water and ether bath, and a sterile towel bandaged over the knee. In the operating room the application of merthiolate or iodin is repeated and the leg and thigh is carefully draped in such a manner that flexion and rotary motion of the knee joint can be performed.

Nothing should enter the knee joint except the instruments, unhandled gauze or small cotton pledgets; never the gloved finger. The choice of incision depends upon the type of operation considered, and in any knee joint condition the operator may find it necessary to inspect the knee through more than one incision. The small curved incision lateral to the patella gives wonderful exposure to the anterior knee joint compartment, and the posterior exposure of Henderson and others will expose the posterior compartment satisfactorily. Lateral incisions are very valuable, but the lateral ligaments are to be avoided as much as possible. Upon opening the knee joint one is greatly relieved if the findings exposed prove the diagnosis. Apparently normal on the first inspection, the joint must be carefully explored, the cartilages pulled and moved about and search made for tags, splits and tears, the fat pad examined, the crucial ligaments, examination for loose bodies, and the defect in the cartilage from which they came. Often the anterior portion of the internal cartilage must be removed from its insertion and pulled forward to discover injury to the posterior portion of the cartilage. Some recommend entire removal of the cartilage if damaged. It has been our experience that if the anterior two-thirds or anterior three-fifths, especially if the cartilage is damaged in this portion, be removed, the symptoms will be relieved. If the cartilages prove to be absolutely normal or are found to be freely movable, I hesitate to remove them because of this free motion alone. The fat pad, which may be enlarged, red and inflamed, should be carefully examined, especially with the absence of damage to other internal tissues of the joint. Enlarged portions of the pad are removed freely with careful control of the hemorrhage usually found after cutting this pad.

Damage to the Tibial Tubercle.—If the tibial tubercle is loose, it is sutured into place by the method of Lee.[2]

Usually the crater in osteochondritis dissecans is carefully saucerized to prevent formation of new loose bodies in the joint, that is if the knee joint proper is opened. If the loose body is removed by incision through the pouch, the area of origin is not treated. Many condemn the refraining from treatment of the crater in osteochondritis dissecans, but I personally have simply removed loose bodies in this condition without new bodies forming and without further trouble to the patient.

Treatment of Injuries to Ligaments.—Following injuries to either or both of the ligaments, full extension of the knee joint should be main-

tained for at least three to four weeks without motion, and the limb held in a rigid apparatus. The apparatus should be of such character, however, that it can be removed so that massage and manipulation and contraction of the quadriceps extensor tendon can be a daily procedure. After removal of the rigid apparatus, a hinge splint or cage splint may be used for two or three months, and then a heavy, soft bandage can be used for protection. If the point of rupture can be demonstrated at the time of injury, early suture of the ligament is indicated, but if after usual care stability does not return, repair of the ligament is demanded.

Repair of Ligaments.—The internal lateral ligament is usually repaired by the use of the tendons of the gracilis and the semitendinosus muscle, freeing them from their insertion, bringing them forward and cutting them at the level of the attachment of the ligament on the condyle of the femur and either suturing or holding them with a metal staple in a groove made in the condyle. The free tendons are sutured to the tendon of the sartorius so the muscle power of these tendons is not lost. The Mauck method of suture or removing the tibial attachment and suturing the flap of bone down on the tibia seems worthy of trial in cases in which there is not a complete rupture of the ligament.[3] There are many other operations for repair of the lateral ligaments.

The external lateral ligament is usually repaired by using a tube of fascia lata, attaching it to the external condyle of the femur in a small bone cavity, pulling it down along the course of the lateral ligament and suturing it to the head of the fibula under strong tension.

Rupture of the Crucial Ligaments.—Operations for repair of crucial ligaments are rare because repair or a fair degree of stability returns after conservative treatment. Like treatment for lateral ligaments, prolonged immobilization in the greater number of cases brings satisfactory results. If, in spite of the usual conservative treatment, marked instablility is present due to rupture of the anterior or posterior crucial ligaments, operation may be contemplated. Most of the operations are copied after the procedure made standard by Hey Groves, that is the use of a strip of fascia lata inserted to take the place of the ruptured ligament. Recently Cubbins and Campbell have perhaps improved the original plan to perfect treatment in this serious injury.[4]

Slipping Patella.—Habitual outward dislocation of the patella is as disabling as other derangements of the knee joint and may prevent the individual from competing in sports or doing manual labor. The old method of Goldthwaite in transferring the tibial tubercle with the attached patellar tendon to the inner side of the tibia is a tried and known procedure. In young children and in adolescents my operation of choice has been reefing of the internal capsule of the knee joint with a strip of fascia attached to the patella and the internal condyle of the femur, the so-called Mouchet operation. Recently Ober has observed an abnormal relationship between the iliotibial band and the patella and concludes that recurrent dislocation of the patella is a mild congenital displacement of the patella. He uses a flap of this band after dissecting loose from above the patella and suturing it through a small tunnel cut into the inner side of the tibia. The operation relieves the pathological anatomy and supplies a tendon which maintains the normal position of the patella.[5]

Fractured Patella—Fracture of the patella with separation requires an operation. Some suture only the capsule, others suture the bone, and a combination of the two methods may be used. Fascia, wire, Kangaroo tendon, and heavy chromic catgut may be the choice of materials used as sutures. Chip or split fractures or comminuted fractures without misplacement are often treated and successfully by apparatus.

Postoperative Treatment

After inspecting a joint for a loose body or removal of a cartilage, care should be taken in closing the wound layer by layer, synovia fascia, capsule fascia and skin. A dry dressing, covered by many layers of sheet wadding, is held in place by a bandage and supported by adhesive. Motion is not restricted and after three or four days is encouraged. Weight bearing is usually allowed after seven days, stitches are removed on the eighth day, and the patient leaves the hospital on the tenth or twelfth day. A soft supporting bandage is worn for two weeks more. Motion is encouraged, and heat and gentle mas-

sage along with active motion may be given for a week or ten days after the hospital discharge with advantage to the patient.

Treatment After Injuries to Lateral Ligaments, crucial ligaments, slipping patella, or evulsion of the tibial spine, requires absolute fixation usually with a splint or a bivalved cast. About the eighth day the stitches may be removed and the retentive apparatus removed for massage, baking and contraction of the quadriceps extensor tendon, except in the case of fracture of the patella. Absolute fixation is necessary in soft parts injuries for at least three or four weeks, followed by supportive apparatus. In bony injuries six to eight weeks or even more of fixation are necessary followed by supportive apparatus. In either case gentle massage and manipulation over the ligaments and soft parts is indicated early.

The Evaluation of Disability after an injury to a knee joint in Minnesota is enumerated in percentage of loss of function of the limb as a whole. A given percentage of loss of function after injury in any case is largely a personal opinion, as evidenced by the frequent discussions before the Industrial Commission. Percentage of disability depends upon the finder's analysis of any given case, usually upon the function of the injured member.

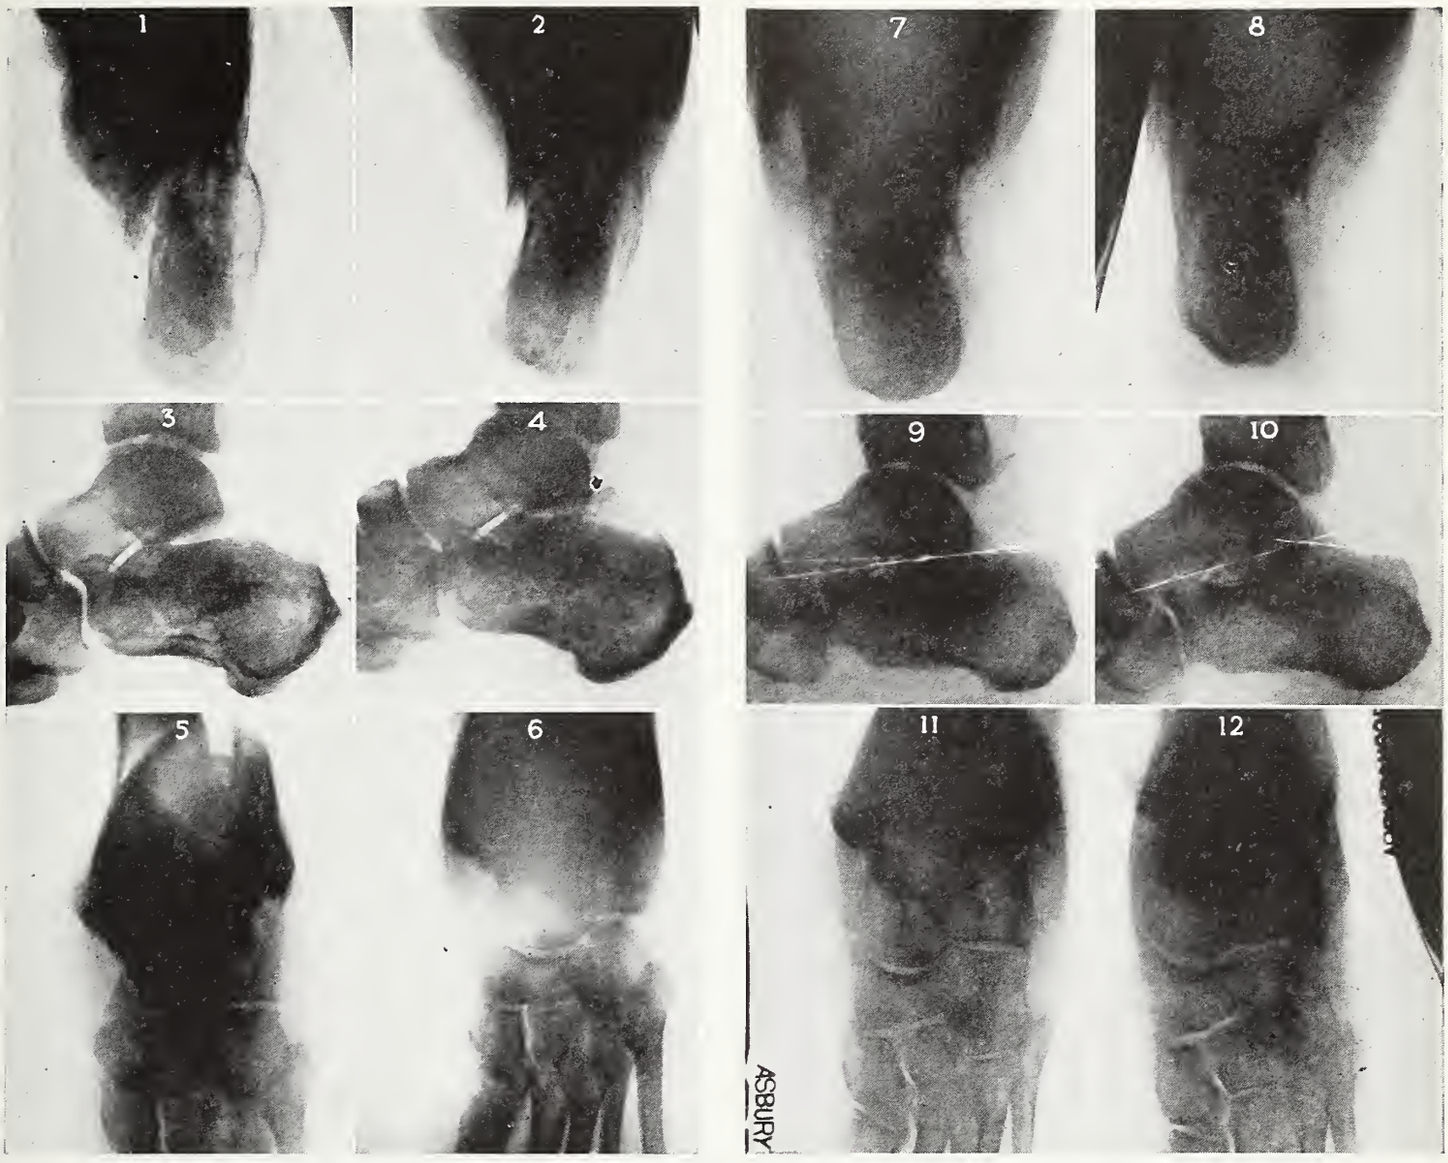
AN IMPROVED TREATMENT FOR OS CALCIS FRACTURES*

O. W. YOERG, M.D.

Minneapolis, Minnesota

BY the use of a method evolved about three years ago we have been able to obtain improved anatomic as well as functional results and, in the ordinary type of os calcis fracture, have been able to return men to work within three months from the time of reduction. In the more severe injuries, particularly those in which there has been a crushing of the posterior joint surface and in which the heel has been driven up and the angle either lessened or lost, convalescence has been slightly increased. But in most of these cases the men have been returned to work within four or five months from the time of reduction.



The method that we are employing consists of manually disimpacting the fracture, bringing the heel down by pulling the sole of the foot, with a sudden thrust, against a firm vertical bar, and the use of an os calcis compression clamp to overcome the broadening of the heel and to replace the loosened bones to their normal or near normal position; this followed by the application of a well molded boot cast.

In a patient with a fracture of the os calcis, the usual lateral and plantar dorsal films are made, and, in addition, an antero-posterior view is taken to visualize the anterior portion of the os calcis. He is then put to bed with the foot elevated, and hot packs employed to aid in the reduction of the swelling and to lessen his pain. Reduction can usually be made in four or five days or a week. Occasionally ten days are necessary but never more than two weeks are allowed to elapse before reduction is attempted.

We anesthetize the patient with a general anesthetic to obtain complete relaxation of the muscles of the leg. The patient is placed on the affected side so that the foot can be brought to the edge of the table, with the heel extended over the edge.

The foot and ankle are now firmly held by the left hand, and with the right hand the heel is manipulated laterally, with repeated thrusts, until the fracture has been thoroughly disimpacted.

*Presented with motion picture and x-ray slides, before the annual meeting of the Minnesota State Medical Association, Saint Paul, Minnesota, May 5, 1937.

Case 1.—P.S.L., aged fifty-nine, a grain elevator foreman, fell October 13, 1936, a distance of ten feet from a ladder, sustaining a fracture of his right os calcis. Reduction was made October 18 and the cast was removed November 20. The patient began to walk on his foot December 12. He returned to light work February 18, 1937, and to regular work March 15. There is a slight limitation of motion in the subastragalar joint.

Fig. 1. Plantar dorsal view shows extensive fracture with lateral displacement of the tuberosity.

Fig. 2. The fracture after reduction, lateral displacement corrected.

Fig. 3. Lateral view before reduction. The posterior joint surface of the os calcis is flattened and the carrying angle negative.

Fig. 4. Lateral view after reduction. The fracture is thoroughly disimpacted and the joint surface brought up. The carrying angle is restored to normal.

Fig. 5. Antero-posterior view before reduction shows a fracture into the anterior portion of the os calcis with moderate displacement.

Fig. 6. Antero-posterior view after reduction, displacement corrected.

Case 2.—J. F. Y., aged sixty, subpostoffice superintendent, on December 2, 1936, fell six feet, fracturing his left os calcis. Reduction was made December 8, 1936, and cast was removed January 6, 1937. The patient began to walk with crutches on February 8, 1937. He returned to work on May 2, five months after the injury. He has worked regularly, on his feet at least six hours a day. Motion is excellent and there is no pain in the foot, but the patient states that calf muscles tire toward the end of the day.

Fig. 7. View of tuberosity before reduction shows a comminuted fracture with broadening and shortening.

Fig. 8. Tuberosity after reduction. The broadening has been overcome and the bone lengthened.

Fig. 9. Laterial view before reduction shows a crushing of the posterior joint surface with the carrying angle zero.

Fig. 10. The posterior joint surface of the os calcis has been brought up, and the angle restored to normal.

Fig. 11. Antero-posterior view shows the front of the os calcis and astragalus, the scaphoid and the cuboid. The anterior portion of the os calcis has been fractured into the os calcis cuboid joint with marked displacement outward under the external malleolus.

Fig. 12. Antero-posterior view after reduction. The fracture of the anterior portion of the os calcis has been reduced and the external malleolus is now clear.

Any upward displacement of the os calcis is corrected by grasping the heel with one hand, the forward portion of the foot with the other hand, and then pulling the sole of the foot with a sudden thrust against a vertical bar. The broadened but now loosened bones are squeezed into place with an os calcis clamp. All of the procedures are done with the knee flexed and the foot in plantar flexion.

A well molded boot cast is applied, with foot in full plantar flexion. Constant traction on the heel is used while the cast is molded under the malleoli, over the back of the heel and under the arch of the foot.

After reduction and the application of the cast the patient is placed in bed, with the foot elevated. He is kept in bed for three or four days, or until his pain has disappeared. Many of these patients, in spite of the fact that the fracture is forcibly manipulated, have little or no pain following reduction. When pain has subsided and we feel that there is no more likelihood of pull from the calf muscles, the patient is allowed to be up and about, using his crutches. He is discharged from the hospital, but is not allowed weight-bearing on the injured foot.

Four weeks after reduction the patient returns and the cast removed. Radiographs will show union taking place and that it is sufficiently strong so that a cast is no longer necessary. The patient is then instructed to massage and actively and passively move the boot and ankle. Particularly is he instructed to evert and invert the foot to bring about a return of motion in the subastragalar joint. He continues this massage and manipulation for the period of four weeks but is not allowed weight-bearing. He returns again at the end of four weeks, or two months after reduction. The radiographs then taken will show that union is firm. He is allowed to walk on the injured foot, using his crutches. In the ordinary type of fracture he does so with little or no pain, and, in a few days or a week, in most instances, will discard his crutches and walk without support.

We have now treated by this method thirty-one patients with os calcis fractures, three being bilateral. Of these, twenty-two have been restored to working capacity: five were returned to work in two and one-half months from the time of reduction, eight in three months, six in four months and three in five months.

We have one failure, in a railway mail-clerk, who fell from a ladder, a distance of twenty feet, and sustained a severe crushing fracture of the os calces of both feet. This was one of the early cases, before we pulled the heel over the vertical bar. I thought at the time we had obtained a good reduction, but I see now that we did not completely reduce the fractures. His right heel is practically well as far as pain is concerned; his left heel still causes him trouble. He has not returned to work but has been working in his yard four or five hours a day, with some pain but not enough to keep him from working.

The accompanying illustrations of two selected cases show the fracture before and after the reposition of the bones by this method.

PHYSICAL THERAPY IN RELATION TO INDUSTRIAL MEDICINE*

FRANK H. KRUSEN, M.D.

Rochester, Minnesota

PHYSICAL therapy, applied intelligently under direct medical supervision, may be of great value in hastening the rehabilitation of those injured in industry. Kessler has pointed out that the end-results of industrial accidents "should be appraised not on the basis of structural changes but on disturbed function." It is in the restoration of function that the use of physical measures is most effective. Some idea of the extensiveness of industrial injuries may be obtained from the estimate of Newquist, who said there were 16,000 accidental occupational deaths during 1935. Of course, the number who were merely maimed or injured were many times this amount.

For the most part, it becomes the duty of the medical practitioner to restore injured work-

*From the Section on Physical Therapy, The Mayo Clinic, Rochester, Minnesota. Read before the annual meeting of the Minnesota State Medical Association, Saint Paul, Minnesota, May 5, 1937.

men to remunerative employment as soon as possible. Shinn has said of industrial medicine that: "Its purpose is to insure good health and prevent injuries, thereby promoting contentment, alleviating suffering and increasing the life span of man. It further deals with the rehabilitation of diseased and injured persons in an effort to insure them a livelihood." It cannot be stressed too strongly that there is great need for all physicians to be familiar with the best and simplest methods of treating the injured workman. As Sir John Simon has put it, "Measures, whether voluntary or compulsory, for the prevention of industrial disease and ill-health depend primarily on the knowledge, skill and coöperation of the medical profession." The objective to be attained in the treatment of all those injured in industry is the return of the involved worker to normal working status in the shortest possible time. This should be desired by the physician and the injured worker, as well as by the employer.

The chief sphere of usefulness of physical therapy in industrial injuries lies in the treatment of the large group of cases in which there has been trauma to bones, joints, muscles, nerves or skin. Hastening of restoration of articular function is one of the most important phases of this work. Another important contribution of physical therapy is in the rehabilitation of the badly maimed worker, who must be reëducated to make the best use of his limited physical capabilities. Frequently, a properly graduated routine, including surgical treatment, physical therapy, occupational therapy, the sheltered workshop, and a new type of remunerative occupation suited to the handicapped patient's limited ability, will make a happy, useful citizen and worker of a potentially permanent invalid.

Occupational therapy which plays an important part in this transition is a form of physical treatment, and properly administered under medical supervision it will aid greatly not only in restoring function but also in improving the patient's morale. Odencrantz has said: "Anything that can be done to help the handicapped build up his confidence, his morale and his ability, increases his opportunity for satisfactory adjustment."

Because of certain psychic factors which enter into the problem of the injured worker, it is essential that all phases of treatment, and particularly the details of physical therapy, be under direct supervision. No opportunity should be permitted for prolonging such treatment until it becomes a habit, and under proper medical supervision this will not occur. Physical measures should be used only when and as indicated and only when they are producing definite objective improvement. Likewise, during the application of these treatments there is an opportunity for the highly important personal contact between the physician and the patient. Eckelberry has said: "The injured workman may be just a file with a name and number in the insurance office, another case on the calendar at the hearing, and an interesting case to the doctor; but he is nevertheless a human being, influenced by his emotions, subject to hate, fear, doubt and gratitude, even as you and I. To obtain the best results in his management he should be treated as a human being."

Among the physical agents which may be applied with benefit in treating industrial injuries are heat, light, water, electricity, massage, exercise and occupational therapy. The employment of these physical measures, in their simplest form and under close supervision, frequently at the patient's home, is highly to be desired.

The physician should never write an order to some lay technician to give the patient "some physical therapy." This is just as ridiculous as if he were to write a prescription to a druggist to give the patient "some medicine," and the results are likely to be equally as unsatisfactory. The order which is frequently written for B. M. and E. (baking, massage and exercise) with no detailed instructions is likely to prove equally futile.

The Council on Physicial Therapy of the American Medical Association has demonstrated that there are many physicial agents which, when employed scientifically, are of great value therapeutically. Unfortunately, many physicians are little acquainted with the proper use of physical agents in treating disease because until very recently this subject was much neglected in the medical schools. At present, the intelligent employment of physical therapy in our hospitals and in private medical practice has done much to combat the charlatan who has attempted to worm his way into industrial medicine as well as other phases of medical practice.

The essentials for proper treatment of indus-

trial injuries by means of physical therapy are: (1) devices for the production of the required physical agents (these should be as simply constructed as possible); (2) a physician skilled in the use of these devices and thoroughly familiar with the effects which they can produce; and (3) in many instances (when the physician does not wish to apply treatments himself) a trained technician who has skilled hands for massage and manipulation and who can also use various apparatus as ordered by the physician.

Light Therapy

Since the early part of the Seventeenth Century, when Isaac Newton discovered that a beam of sunlight could be split by means of a prism into the various primary colors, a series of subsequent discoveries have developed a huge electromagnetic spectrum with varying physical properties which physicians have learned to use in treating disease. Below the red end of Newton's rainbow were found invisible infra-red (heat) rays, and above the violet end were found invisible ultraviolet (chemical rays). Below the infra-red rays are hertzian waves, which physicians now utilize for short-wave diathermy. Above the ultraviolet rays lie the roentgen rays (physical rays whose therapeutic value is familiar to all physicians), and beyond these lie the gamma rays of radium (the therapeutic value of which is also well known).

Today, the injured workman may be instructed to buy a simple heat lamp which will produce either near or far infra-red rays for medical treatment. These infra-red lamps (heated by resistance coils) do not vary greatly from the ordinary household heater with the exception that the latter has a wider reflector which diffuses the heat through the room, while the therapeutic lamp has a more convex reflector which localizes the radiation of heat on the bodily surface. The so-called infra-red units (heated coils or plates) and luminous bulbs (carbon or tungsten filament lamps) may be used in the same convex reflector. The former produce less penetration of heat and more surface heat; the latter produce more hyperemia and slightly more penetration. Large lamps which have big reflectors may be used to treat extensive lesions. For use in the home, a simple home-made baker may be constructed by any tinsmith at a cost of two or three dollars. These various heat lamps will be found extremely valuable in producing surface hyperemia to relieve the pain of sprains, contusions, fractures, and certain inflammatory lesions.

In indolent wounds and in certain types of ulcerations and lesions of the skin, the ultraviolet rays produced by a mercury quartz or by a carbon arc light may be found useful.

Time does not permit a complete consideration of all the indications for the use of light rays in industrial diseases; nevertheless, many uses are known.

Heat Therapy

One of the simplest and most effective methods of applying heat locally is by means of the paraffin bath. Extremities may be dipped in melted paraffin, a coating of which is left on the part for twenty to thirty minutes. A glove or boot of paraffin is formed, which may be stripped off with ease at the end of treatment. This leaves a marked hyperemia of the skin. The paraffin may be painted on a shoulder, arm or back and later removed, leaving a warm reddened skin which is ideally prepared for massage.

Hydrotherapy

One of the easiest ways of stimulating peripheral circulation is to apply the time-honored contrast baths. These are applied to the extremities, by using buckets or pans as containers for the hot and cold water. If a shoulder or some portion of the trunk is to be treated, an ordinary bath spray may be used to apply hot and cold water alternately to the affected region. This will produce effects comparable to those achieved by immersion contrast baths.

Whirlpool baths (baths of whirling, aerated water at a temperature of 110° F.) are excellent for the auxiliary treatment of fractures, preliminary to massage and therapeutic exercise. These baths may be constructed for a few dollars by any plumber (specifications may be obtained from the Secretary of the Council on Physical Therapy of the American Medical Association).

Recently, underwater exercises have been used not only for the treatment of poliomyelitis but also for the treatment of extensive trauma. The patient is placed in hot water in a specially constructed tub known as a Hubbard tank. In this

hot water the muscles usually relax, and massage is administered under water during the period of maximal heating. Exercises under the water are readily performed because of its buoyancy and it is possible to secure activity in all planes.

Electrotherapy

The use of short wave diathermy, although much exploited, nevertheless must be considered favorably in the treatment of many types of deep trauma to soft tissues. The effects are explained merely on the basis of heating of the tissues, but this heating has been proved to reach to deeper levels than can be obtained by any other means of application. In most instances, an induction coil, cuffs, or air-spaced electrodes should be applied to the area to be treated.

Massage and Corrective Exercise

Stevens in discussing the use of physical therapy in industrial injuries pointed out that by far the most valuable service which such therapy renders is in "the preservation and restoration of joint function." He believed that the technician skilled in massage and manipulation was the "sine qua non of the physical therapy set-up." In this I can heartily concur. I agree also with certain of his conclusions, namely, that "joint restriction can often be prevented by early motion which stimulates rather than hinders repair"; that "the use of apparatus has definite value but only as a preliminary to skillful manipulation at the hands of the physician or well-trained technician"; and that "active use of the part, preferably under the supervision of an occupational therapist, is a necessary supplement to other physical therapy procedures."

Occupational Therapy

Occupational therapy should be administered in conjunction with other physical measures. Devices such as the shoulder loom may be used to hasten the return of articular function in a most agreeable manner. Occupational therapy plays an important part in reëducating those who have been severely maimed in industrial accidents. Stroud has said: "The majority of the handicapped who may be rehabilitated and placed in industry are those with cardiovascular, arthritic and orthopedic disabilities." He has recommended training in occupational therapy followed by work in sheltered workshops as a means of fitting patients for suitable industrial positions. Eckelberry has said, "One of the greatest aids in rehabilitation is the opportunity for the workman to resume work of a lighter character than his usual job and . . . gradually to approach the same work and activity he enjoyed prior to the accident."

Conclusions

1. The use of physical therapy may be of considerable value in the treatment of industrial injuries.
2. This type of therapy is particularly applicable to the hastening of restoration of function following trauma and to the rehabilitation of the severely handicapped patient.
3. The application of physical measures should be under close medical supervision, and specific instruction concerning treatment should always be given.
4. Many simple physical devices may be utilized in treating industrial injuries; these devices may frequently be constructed for home use.
5. Massage and manipulation must always be performed by skilled hands.
6. Occupational therapy in conjunction with other forms of physical therapy plays an important part in the rehabilitation and return to industry of the severely handicapped worker.

CASE REPORT

HYSTERICAL DYSPHAGIA*

HERBERT W. SCHMIDT, M.D.
Rochester, Minnesota

THE most common conditions which cause dysphagia in the superior portion of the esophagus are:

1. Intrinsic lesions of esophagus:
   a. Carcinoma
   b. Benign stricture
   c. Pharyngo-esophageal diverticulum with secondary esophageal stenosis
2. Neurologic lesions:
   a. Bulbar palsy
   b. Amyotrophic lateral sclerosis with bulbar involvement
   c. Infantile paralysis with bulbar involvement
   d. Myasthenia gravis
3. Extrinsic lesions:
   a. Laryngeal lesions
      (1) Inflammatory
      (2) Neoplastic
   b. Tumors of the neck:
      (1) Goiter
      (2) Other tumors
4. Foreign bodies
5. Functional conditions:
   a. Functional dysphagia
   b. Hysterical dysphagia

Hysterical dysphagia was so named by H. S. Plummer, in 1914, because he believed it was a functional disturbance, of a hysterical nature, which involved deglutition.

This syndrome is characterized by a difficulty in swallowing and is associated with a hypochromic anemia; it occurs among women and there is no definite evidence of organic obstruction in the esophagus. The patients describe a dysphagia which begins suddenly, and usually is as pronounced at the onset as at any time in its course. The patients have the greatest difficulty in swallowing solid foods; they say that solid foods will not go past the level of the cricopharyngeus muscle. This difficulty may become extreme. In a recent case that was reported, the patient said that she would strain the juice from strawberry sauce to get rid of the seeds and would dilute and then strain buttermilk to get rid of the curds before ingestion, because she was afraid they would lodge in the upper portion of the esophagus and strangle her. Swallowing of pills and capsules, no matter how small, causes a great deal of trouble. Most of the patients have false teeth, and fissures at the angles of their mouths. There frequently is a glossitis which is associated with atrophy of the lingual papillæ, which gives the tongue a red, glazed appearance which resembles the type seen in pernicious anemia. In about a third of the cases the spleen is palpable; most of the patients have an achlorhydria. It is felt that the changes in the mucous membrane and the splenomegaly are secondary to the rather severe prolonged dietary restrictions and resulting anemia.

These patients can be cured by passing an esophageal sound into the stomach over a previously swallowed silk thread, and subsequently given a good deal of reassurance. As Dr. Moersch has pointed out, this strengthens the theory that the condition is primarily of a functional nature, since the size of the sound passed is immaterial and the esophagus is not stretched.

Report of Case

The patient was a woman, forty-five years of age, who for about twenty-five years had had more or less difficulty in swallowing food. She said that a "hurting sensation" would develop in the region of the pyriform sinuses, on swallowing. She had deep fissures at the angles of her mouth and a sore tongue which had caused her much anxiety and concern. An anemia had been found ten years previously; the value for the hemoglobin had ranged from 46 to 53 per cent and the number of erythrocytes had varied from 3,800,000 to 4,360,000 per cubic millimeter of blood. An achlorhydria had been discovered, and the possibility of pernicious anemia and Banti's disease had been considered. She had been placed on a high vitamin, high caloric diet and dilute hydrochloric acid had been administered. This treatment had produced improvement in her general physical condition and blood findings.

In May, 1936, she was seen at the clinic and said that for one year she had had an increase in the difficulty in swallowing, which had become so severe that she had been unable to swallow aspirin tablets or even small pieces of meat because she had felt that the "opening in her esophagus was simply too small."

Examination disclosed a pale, white woman. She had false teeth, fissures at the angles of her mouth, and a red, smooth, beefy tongue. The value for the hemoglobin was 12.9 gm. per 100 c.c. of blood and there were 4,520,000 erythrocytes in each cubic millimeter of blood. Special blood smears showed nothing diagnostic. She had an absence of free hydrochloric acid in the gastric contents. The spleen was palpable. A rather large adenomatous goiter was present but there was no sign of hyperthyroidism. Her basal metabolic rate was found to be +3 per cent. It was felt that, in view of her age, the goiter should be removed. The possibility that the goiter might be a factor in the causation of her dysphagia also was considered. A thyroidectomy was performed and she made an uneventful convalescence. Her dysphagia, however, failed to improve. It was then recognized that she had a true hysterical dysphagia. A No. 41 French sound was passed into the stomach; no obstruction was encountered. After the immediate effect of the passage of the sound she was able to swallow all types of foods without difficulty. Iron and ammonium citrate was given by mouth and three months after the passage of the sound the patient did not have any dysphagia.

Bibliography

1. Moersch, H. J., and Connor, H. M.: Hysterical dysphagia. Arch. Otolaryngol., 4:112-117, (Aug.) 1926.

*From the Section on Peroral Endoscopy, The Mayo Clinic, Rochester, Minnesota. Read before the annual meeting of the Southern Minnesota Medical Association, Winona, Minnesota, August 11, 1937.

CHAIRMAN MUSSEY: It was suggested that a question conference or question panel be held in obstetrics and gynecology as a sort of trial flight this year. We have several men who are interested in obstetrics and gynecology or both, who have kindly consented to carry on this conference. The answers to these questions will be limited to two or two and one-half minutes, if possible. We aim to get through a fair number of them in the time allotted to us.

The first question will be answered by Dr. Randall:

"Of what value is prepartum care?"

DR. L. M. RANDALL (Rochester): I think the answer to this question probably is obvious to all of you, but those of us who are practicing obstetrics and gynecology feel that too much emphasis cannot be placed upon the prenatal care of the obstetrical patient.

To me, it has always seemed that this type of preventive medicine, which it is, is essentially an invoice of the patient's physical, mental and nervous assets and liabilities.

It has been shown, of course, in a great number of patients who have had what we consider to be adequate prenatal care, that the incidence of complications of pregnancy, labor and the postpartum have been reduced by one-half. We all realize that, if a patient is seen early in pregnancy, the blood pressure is taken routinely, the urine examined and pelvis measured, that we are in a much better position to guide that individual through a pregnancy than we are in the patient that we see when she is already in labor and have not had an opportunity to check these things.

In considering the blood pressure readings, it has been found that those patients who develop toxemia show first an elevation of blood pressure.

Some criticism has been made that the examinations of these patients with toxemia or suspected toxemia are too complicated.

I think, on the whole, if one reviews the situation, it will be found that the tests that will detect the presence of this condition are relatively simple: blood pressure readings, examination of the urine, and checking the patient's weight, leaving out the more complicated laboratory procedures.

I think we all need to emphasize to the patient, and I suppose to ourselves, that the chief thing to consider with these people is to see them early and do the essential, simple, routine examinations that we believe form the part of adequate prenatal care.

CHAIRMAN MUSSEY: This question is for Dr. Litzenberg:

"Is radical treatment, that is, therapeutic abortion or cesarean section, often necessary in heart lesions during pregnancy?"

DR. J. C. LITZENBERG (Minneapolis): Therapeutic abortion and cesarean section in heart disease are almost never necessary. The attitude towards this subject has been very rapidly changing, ever since the internists have crystallized their ideas about the treatment of the heart.

The treatment of the heart in pregnancy is the treatment of the heart, and not therapeutic abortion or cesarean section. At the University Hospital we rarely do a cesarean section for heart disease, and we almost never do early therapeutic abortions.

It can all be summed up very briefly: If every woman is examined when she comes in as to her heart condition, and then every woman with a damaged heart is treated as to the heart, a therapeutic abortion will almost never be necessary. As a matter of fact, the internists have greatly advanced in the treatment of the heart during the last decade or fifteen years.

With this modern heart treatment, if a woman does not improve under the best medical supervision, then a therapeutic abortion may be considered. Even if a woman comes in during later pregnancy and has not been properly treated before, she almost always responds to the modern treatment of the damaged heart, and cesarean section will almost never be necessary. The only operative procedure that is necessary in most of these cases is that the labor be shortened as much as possible after complete dilatation, of the cervix. Then forceps may be applied, but I have been surprised at the rapidity of the labors in these heart cases, and in most of them we don't even use forceps.

The whole question may be summed up in one sentence: The damaged heart in pregnancy should be handled by treatment of the heart and not by obstetrical interference, except to shorten labor.

CHAIRMAN MUSSEY: The next question is for Dr. Rothrock:

"What are the indications for forceps delivery?"

DR. J. L. ROTHROCK (Saint Paul): The indications for forceps delivery are several. Uusually, having watched the progress of labor, if we come to a time when there is no further progress, then it becomes necessary to consider the possibility of the necessity of delivering the patient with instruments.

Before this is done, it is very desirable to have, in your prenatal care, thoroughly examined the patient and to have made an exhaustive examination to know whether it is possible to deliver her with instruments. Prolonged labor is often the result of inertia of the uterus. The patients become exhausted. To allow them to go longer, perhaps, would be to their detriment. It is necessary to watch these patients, particularly, and to observe the time when it becomes desirable to interfere.

In cases of prolonged labor, it is particularly desirable, also, to handle your patients with extreme care, to prevent the possibility of infection, to eliminate, as far as possible, unnecessary examinations, and to look forward to the possibility that the patient, even though you successfully deliver her, if she becomes infected, will be in danger.

Another indication is the watching of the fetal heart sound to know whether the infant, the unborn child, is in danger. Sometimes it becomes necessary to suddenly terminate a labor with instruments, because of distress of the infant in prolonged labor.

The question is one which requires the greatest judgment, inasmuch as a certain number of borderline cases require reliance upon the so-called test of labor. How long should we permit a woman to go before we think of interfering? That depends on the condition of the patient. I would say that it may be summed up in this procedure: to carefully watch the patient, and, after there has ceased to be any progress in labor for

a certain length of time, then to increase our vigilance, and, before the patient becomes exhausted, or before the fetal distress manifests itself, to prepare to interfere with the instruments.

CHAIRMAN MUSSEY: The next question is for Dr. Manley:

"If you were called to see a woman in shock in whom you suspected tubal pregnancy, how would you handle the situation?"

DR. J. R. MANLEY (Duluth): In handling tubal pregnancies, there has been, in the past, two classes of men, one who believed in waiting, and one who believed in operating. My practice has been to take care of these cases as soon as the diagnosis is made.

With one or two exceptions, the first thing to do in a case of ruptured tubal pregnancy is to transport the patient to the hospital, if possible, and give a little morphin. While waiting for the operating room to get ready, a blood transfusion or glucose intravenously should be given.

I believe the shock in tubal pregnancy is due to hemorrhage. and the logical thing to do is to stop the hemorrhage as soon as possible. A blood transfusion should always be available and may be given before, during, or after the operation. The first object during the operation is to deliver the ruptured tube and stop the bleeding. Then you may remove organized clots and complete the operation. It is not necessary or advisable to spend time removing all the blood.

CHAIRMAN MUSSEY: Dr. Hartley will answer this question:

"What are the indications for version?"

DR. E. C. HARTLEY (Saint Paul): Version is one of the oldest obstetrical operations. There are two kinds, depending on which end of the fetus you intend to cause to engage. If the head is brought down, then it becomes cephalic version. If you want to make the breech present, it becomes a podalic version.

Cephalic version is attempted when the breech presents. This may be done by external manipulation and, if it can be done, it is very desirable. If it is too difficult, it probably isn't worth doing. Often if done, unless the head can be made to engage at once, it will not stay in place.

The commonest type is podalic version. This means inserting the hand into the uterus, grasping one or two feet and bringing them down to the outlet. By means of this maneuver it is possible to convert such presentations as face, brow or shoulder into one relatively easy to deliver. For other reasons, such as hemorrhage, it may be desirable to get something down in the cervix so that delivery may be done almost at the discretion of the obstetrician.

There is a type of uterine inertia which several men have described, in which long labor finally results in the complete dilation of the cervix and yet the patient doesn't deliver. If this condition can be accurately determined in advance, and we know for certain that there is no bony obstruction, a podalic version may often be done with surprising ease.

CHAIRMAN MUSSEY: Dr. Rothrock:

"What are the outstanding indications for cesarean section?"

DR. J. L. ROTHROCK (Saint Paul): The outstanding indication for cesarean section is a disproportion between the size of the baby and the pelvis. In other words, the most important indication is found in those patients with contraction of the pelvis. It used to be said that there were absolute indications, and indications which were under the title of emergencies. The absolute indication was a pelvis where the inlet was 7 centimeters or less. Today we recognize the fact that with inlet contraction there are a number of cases where the inlet is much more than 7 centimeters, yet the size of the head of the infant will not pass.

Then, too, we have to take into consideration contractions at the pelvic outlet, which are quite frequent. There have been added many indications for cesarean section. For example, the question of central placenta prævia in a primipara with a rigid cervix, in my opinion, becomes a perfectly justifiable indication for cesarean section. There are certain indications which arise, where it is desirable to deliver the patient, as, for example, in cases of toxemia. They are very few, however.

The premature separation of the placenta, especially the more severe form, also forms an indication where hemorrhage is going on and where, if the patient's condition is at all suitable for an operation, then sometimes the only method of rescuing that patient is to deliver as quickly as possible, and that can be done in case the patient is not in labor, by a cesarean section. These form some of the indications.

It is true that in recent years the application of cesarean section has been much extended, and some of the indications which have been alleged, have, in my opinion, brought about a situation in which far too many cesarean sections are made where the patient might be more safely delivered by other methods.

CHAIRMAN MUSSEY: Dr. McKaig is next:

"How would you manage asepsis in a farm home delivery?"

DR. C. B. MCKAIG (Pine Island): My practice being mostly among the farmers makes quite a lot of difference in the handling of asepsis. The first thing I see to is that my instruments and gloves are sterilized at home in a pan contained in my grip with a good tight lid on it. The main reason for the lid is to keep the dust and flies out after you arrive at the patient's home.

The patient is scrubbed up with a combination of liquid soap and 1:2500 metaphen, half and half, which gives you a good lather. She is washed up, the legs and all sterilized but not shaved. Then after drying, the legs and vulva and parts are thoroughly sprayed with tincture of metaphen by means of an atomizer. Incidentally, at that time I strap a flashlight on the leg with adhesive plaster, so as to give me plenty of light. Usually the light isn't very much good in farm homes.

One of the main things is to impress the people that they should leave everything alone, not to handle any of the instruments, which they are very apt to do, picking one up and asking the doctor, "What is this for?" Then you have to do your sterilizing all over again.

One of the chief managements for asepsis is to do as little vaginal examination as possible. Do most all of your examination by way of rectum, keeping track of progress in that way. I carry impenetrable pads and waterproof dressings for the bed.

CHAIRMAN MUSSEY: After the program was printed, Dr. Wahlberg kindly consented to take part in this conference. The question has come in:

"What is the most acceptable treatment for preeclamptic toxemia and eclampsia?"

Dr. E. W. Wahlberg (Morgan): The treatment of preeclamptic toxemia, as you know, may be divided into prophylactic and active treatment, both of preeclamptic toxemia and the eclampsia.

Dr. Randall mentioned some of the indications in prenatal care. The outstanding features of the value of prenatal care in the prophylaxis of preeclamptic toxemia are the routine examination of the blood pressure, urinalysis and the recording of weight, and the recording of these so that one may detect early the development of preeclamptic toxemia and take proper steps.

How should preeclamptic toxemia be treated? In the first place, it must be considered as a medical condition to be treated by medical measures primarily. Any other measures, such as the interruption of pregnancy, are secondary to the medical measures.

In the consideration of preeclamptic toxemia, it may be considered as a disease that progresses from mild to severe forms. In other words, when we have a patient who develops a slight hypertension, with edema, and some albuminuria, even if this is very mild or slight, treatment begun then may prevent the development of a higher blood pressure and more severe symptoms.

The treatment at that time consists of bed rest, laxatives and, what is very important, sedatives, the use, if the condition progresses, of intravenous glucose and magnesium sulphate solution.

I must hurry, so I will go into the more severe form that may culminate in eclampsia: You may not have seen the patient before. Particularly in those cases where the patient is possibly far from the hospital, or where the patient has to be taken into the hospital, the very most important thing is the use of morphin sulphate in a dose of ¼ to ½ grain and used every half hour or every hour until the patient's respirations get down to 10 or 12. This will control a great many.

In the hospital, the use of intravenous glucose, the use of magnesium sulphate solutions intravenously, and other sedative measures, are carried on before any attempt is made to interrupt the pregnancy. That is the important thing. If interruption of pregnancy is determined upon, it should be done, if possible, after the patient has recovered from the acute condition, which is shown by diuresis, regaining consciousness and sweating. If cesarean section is done, it should be done on objective indications, after medical measures have been tried.

Chairman Mussey: Dr. Manley:

"What are the symptoms in early carcinoma of the cervix?"

Dr. J. R. Manley (Duluth): The trouble with carcinoma of the cervix is that the symptoms do not become evident early enough. The public are pretty well trained now to see the doctor if they have postmenopausal bleeding, or if they have bleeding to any extent between their menstrual periods.

My experience is that when people come to me with that story and I look at the cervix and a carcinoma is found it is not early any more; it is almost too late to do anything. I think we have to train our patients to notice other symptoms besides bleeding. If women were trained to notice any alteration in the leukorrheal discharge which they may have had for years, just a little change in its character, a little burning, and would then come for examination, we might be able to do more.

I believe we should examine all women who come to our office, no matter what they come for. If they come for stomach ache or neuralgia, ofttimes a well directed question or two will make them willing to submit to a pelvic examination. Many women will welcome that suggestion. They do not care to ask for it because they think their symptoms are insignificant. But we can accomplish a great deal towards diagnosing early carcinoma of the cervix by educating people.

After they come, it is up to the doctor, then, to decide. The gross cases we see often enough, and it is too late, but it is the small, early ones that we do not get a chance to examine, and therefore we haven't much experience in diagnosing them. The Schiller test is one of the late methods. In my experience, it has not been of a great deal of value because it is positive in erosions and various other conditions. The Schiller test is of value only in very early lesions before there has been any breaking down of the surface epithelium, and even then a positive reaction may not always mean a carcinoma. But if our attention is called to the possibility of making an early diagnosis and we make a study of the Schiller test, we may be able to spot a few of these real early carcinomas which are evidenced by just a little, pale, thickened area in the cervix, before the mucous membrane has been eroded. That is the chance that we have to cut down the deaths from carcinoma of the cervix.

Chairman Mussey: We have the following hypothetical question:

"If I had a patient with occiput in the posterior position on the first labor and had only about six fingers of dilatation of the cervix after thirty hours of labor, how should I handle the situation?"

Dr. J. L. Rothrock (Saint Paul): One of the most difficult propositions the obstetrician has to deal with is the occipitoposterior position, that is the occiput, which normally rotates anteriorly, sometimes rotates posteriorly, owing to the position of the child or to some fault in the mechanism of the labor.

The question then is what to do for this case, if it is observed early. In the first place, the first stage of labor is going to be quite normal because before any rotation possibly could take place the occiput must reach the floor of the pelvis. Almost all of these cases, if permitted to go on under careful supervision, will reach a point when the cervix is dilated.

The question of interference does not arise until the cervix is fully dilated and the head gets to the floor of the pelvis. Then the proper procedure is to conserve that patient's strength, to give her morphin to relieve the pains, and to watch her carefully, and, when the cervix is dilated, then comes the time for assistance.

It is possible sometimes in these cases, by introducing the blade of the forceps after the head has descended to the floor of the pelvis, to cause an interior rotation. In some cases the head becomes impacted, and then it is necessary to deliver with the occiput posterior.

These cases are disastrous in view of the fact that they are apt to cause deep lacerations, and, for this reason, if for no other, the patient should be permitted to go on, as far as she can with safety to the mother and the child.

I do not believe that it is necessary in these cases, as has been recommended, to resort to more radical forms of treatment, as, for example, that some of these cases should be delivered by cesarean section. I do not believe that.

CHAIRMAN MUSSEY: Dr. Randall:

"What governs the premenstrual phase of the menstrual cycle, and what happens if this is insufficient?"

DR. L. M. RANDALL (Rochester): The hormone of the corpus luteum, now known as progestin, governs the premenstrual phase of the menstrual cycle. This hormone is secreted by the corpus luteum and produces the secretory or premenstrual phase of the endometrium. It likewise not only governs the premenstrual phase of the menstrual cycle but governs the integrity of the pregnancy in the early months, before the placenta is capable of performing its own function. A lack of the corpus luetum hormone will produce sterility, a typical menstrual bleeding, and abortion.

CHAIRMAN MUSSEY: Dr. Hartley, the question has come in:

"Can you tell me something about the prenatal care, or, rather, the refresher courses in obstetrics and pediatrics that are contemplated for the state?"

DR. E. C. HARTLEY (Saint Paul): The refresher courses which have been started in Minnesota by the State Department of Health, working with the State Medical Association and the Extension Division of the State University, have been begun, on the one hand, because the physicians in the country as a whole have favored such a development, and, in the second place, because funds are now available for a purpose of this kind. These funds are made available through the Children's Bureau under the Social Security Act. Courses of this kind are being given at the present time in a number of states throughout the country.

In Minnesota we started in during the winter, after preliminary arrangements with the officers of the State Association. The general manner of presentation is as follows: We have decided that a series of six lectures, covering the most interesting or important phases of obstetrics and pediatrics, would be offered. Six obstetricians and six pediatricians were selected. These twelve men together gave the first series at the University this winter. They were given there with the idea that this would work out as sort of a demonstration as to the value of the work not only to the physicians but also as a demonstration of the technic to those who were giving it.

Having completed this series with a fair amount of success, it was decided that, in giving this series throughout the state, six more obstetricians and six more pediatricians would be added, making twelve in all. These six lectures will be repeated in six different centers throughout the state, beginning on the twenty-sixth of May and ending with the end of June. The centers chosen are, Worthington, Mankato, Fergus Falls, St. Cloud, Brainerd and Grand Rapids.

It is hoped that the course will be repeated next year.

CHAIRMAN MUSSEY: Dr. Litzenberg:

"What type of pelvic contraction is most common in Minnesota?"

DR. J. C. LITZENBERG (Minneapolis): Pelvic contractions are dependent upon early, bad nutrition. Minnesota being a rural state and a "Scandinavian province," the children of our Minnesota women, when they have grown up, haven't had to go through a childhood of poor nutrition. For that reason, we have a low percentage of rachitic pelves and general contractions of the inlet of the pelvis; we have enough, but not as many as they do in parts of the country where they have Southern European immigrants.

In this state the contracted outlet is the most common contraction and I wish to pay particular attention to that. We are too apt to observe in our measurements only the contractions of the inlet. It is very easily detected, not only by special measuring devices but by measuring the width of the outlet by the simple device of the doubled fist. You may see that I have gained a little in weight in the last thirty-five years but that fist measurement of 8½ centimeters has never changed, because it is a bony measurement.

Every patient that I see has that outlet measurement taken with that fist. If the fist goes in between the tuberosities of the ischium with ease, I know that woman hasn't a contracted outlet. If it is tight or impossible to shove the fist in between the tuberosities of the ischium, at the level of the anterior border of the anus, I know I must give particular attention to instrumental and more careful measurements of the outlet.

There has been evolved by experience a rule, "the rule of fifteen," which is very easy to remember. If the measurements between the tuberosities of the ischium is 8 centimeters, the chances are very great that that is a normal outlet, but if it is less than 8 centimeters, then it is necessary to take the posterior sagittal measurement, which is that measurement from the tip of the sacrum (not the tip of the coccyx) to the line which runs between the tuberosities of the ischium, at the level of the anterior border of the anus.

So, if the measurement made from the tip of the sacrum to this line, added to the transverse measurement, equals 15 cm., then that outlet is capable of permitting a normal child to be born.

As to the treatment, that is a very long story. The Sims position or the exaggerated lithotomy posture may increase the outlet sufficiently to permit spontaneous delivery. If the contraction is marked, cesarean section, of course, had better be performed before a trial of labor has proven delivery impossible. When the head has reached the pelvic floor it is too late for a cesarean operation.

CHAIRMAN MUSSEY: Dr. Wahlberg, may I ask you this:

"How do you manage to get the woman in the smaller town, or in the country, to come to you for prepartum care?"

DR. E. W. WAHLBERG (Morgan): The newspapers and magazines are stressing the importance of prenatal care constantly, and most of the younger women today realize the importance of it. I think the chief drawback in country practice in getting people in to see us, is the fact that so oftentimes an extra charge is made for these individual calls.

I have gotten around that by increasing my basic charge for my confinement, and then it is up to the individual woman to either take it or leave it. Usually they will take it because they feel they are losing money if they do not come in for these visits and examinations. I think you can give just as good prenatal care in the country as you can in the city.

I usually average about six visits per patient, before delivery. The first visit includes a complete physical examination, including measurement, blood pressure, hemoglobin, and also blood Wassermanns on my new patients. In later visits I simply take the blood pressure, weight and urinalysis, except the sixth and eighth months, when I also do an external abdominal examination to determine the position of the fetus.

I don't think anyone has any difficulty in getting

their patients in. If you offer them something extra for their money the patients by word of mouth will soon spread the gospel around, and the ladies will flock to your door.

CHAIRMAN MUSSEY: Dr. Hartley:

"Puerperal sepsis is said to be the commonest cause of material mortality. What can be done about this?

DR. E. C. HARTLEY (St. Paul): During the ten-year period ending in 1932 for the United States as a whole, about 37 per cent of all the maternal deaths were caused by sepsis. During 1936 in Minnesota, of the 198 maternal deaths, 35 per cent were caused by sepsis. Apparently the deaths from sepsis both in Minnesota and in the country as a whole run pretty close to slightly over one-third of all maternal deaths.

These are fairly evenly divided between deaths due to infected abortions and to puerperal sepsis. Regarding the deaths from abortions, probably the bulk of these are due to criminal abortions, and they are out of our hands except as to methods of treating them.

The spontaneous abortions rarely end in death provided they are not neglected. Puerperal sepsis is often thought of as being something that might well be laid at the door of the medical profession; there are, however, reservations to any such a viewpoint. There is, nevertheless, much agitation and much organized effort at the reduction of maternal mortality, particularly that due to sepsis. How can such deaths be avoided? In general it may be said that these deaths may be avoided by avoiding infecting the patient or traumatizing her unnecessarily.

This can be done by having the patient go into labor with the attending physician knowing as much about her as possible. In other words, don't try to find out the size of the pelvis after the patient is in labor. Don't make numerous pelvic manipulations when the patient is in labor. Remember that in prolonged labor rest and nourishment are of vital importance to the patient.

CHAIRMAN MUSSEY: Dr. Manley:

"If the pregnant woman has a tumor of the uterus, does this tumor often seriously complicate labor?"

DR. J. R. MANLEY (Duluth): This question could almost be answered categorically, "No." The only tumors you might be afraid of would be the ones down by the cervix. As the cervix dilates, the cervix pulls up around the head, rather than the head going through the cervix. Nine times out of ten it will pull the tumor up beyond the head, so there will be no obstruction to the delivery of the head. Like everything else, there may be exceptions to this.

It is quite possible that a fibroid, perhaps on a pedicle, might get down below the head and obstruct delivery. Small fibroids in the body of the uterus may interfere with contraction pains. They may cause postpartum hemorrhage, but as a rule they do not cause any trouble with the actual delivery. They may become necrotic after delivery and produce trouble in that way.

I had a recent case of that sort in which a large fibroid was let alone during pregnancy. During the puerperium, the patient had fever and swelling of the fibroid and tenderness, but it finally subsided. Later the fibroid began to grow again and was removed, and there was definite evidence of necrosis in the fibroid. But as far as actual difficulty in delivering the baby, it does not very often happen.

CHAIRMAN MUSSEY: Dr. McKaig:

"What would you do for pain relief in a long, tedious labor in a private home?"

DR. C. B. MCKAIG (Pine Island): Long, tedious labors are handled in the home by first giving some sedative. I usually use chloral, about 10 grains, let the patient alone for a couple of hours, then use nembutal. Later on I resort to the Reynolds chloroform inhaler, which the patient can take herself, and she gets a great deal of relief, without anyone in attendance watching that particular case.

CHAIRMAN MUSSEY: Dr. Randall:

"To what extent is it safe to use analgesia during labor?"

DR. L. M. RANDALL (Rochester): The lay press and the medical press has been full of articles on pain relief, in the last few years. The pendulum, I think, has definitely swung from the idea that a woman in labor was not to be given any relief from pain, to the opposite extreme, which is perhaps worse, of giving the individual at the onset of labor a sufficient amount of sedative to produce complete amnesia and lack of coöperation.

This condition definitely raises the incidence of obstetrical operations and I think in the long run will increase the maternal and infant mortality. Far be it from me to say the patient is to be denied pain relief. But in between these two extremes is the safe zone in which we can give the patient reasonable relief from pain, retain her coöperation in the second stage and reduce considerably the risk of this analgesia to the mother and to the baby.

It has been said, of course, that the ideal obstetrical analgesic should be perfectly safe for the mother and for the baby. That analgesic has not yet been discovered, so far as I know.

CHAIRMAN MUSSEY: Dr. McKaig:

"I would like to know of a satisfactory method of episiotomy in the home."

DR. C. B. MCKAIG (Pine Island): Out on the farm, trying to do your work without assistants or without anesthetists, you are up against it. My method of episiotomy in that case is to put in through-and-through stitches previously, before I do any cutting. I put in a row of about four or five stitches with No. 3 forty-day chromic catgut. They go right through the mucosa, into the vagina and back out again, making a row. Then the loops inside are caught with a pair of forceps, drawn out and pulled to one side. The incision is made right in between the stitches.

After delivering the placenta, it is easy enough to pull up and tie the stitches. I have found it very satisfactory in a series of thirty-seven cases.

CHAIRMAN MUSSEY: Dr. Litzenberg:

"What is the difference, if any, between the treatment of carcinoma of the cervix and carcinoma of the body of the uterus?"

DR. J. C. LITZENBERG (Minneapolis): There is a very general consensus of opinion regarding the proper treatment of carcinoma of the cervix, and that is that it is better treated by irradiation than by operation. This irradiation does not mean treatment by radium

but it means treatment by radium and deep x-ray therapy.

Very briefly, the rules of the Cancer Institute for the treatment of cancer of the cervix are these: We follow the Schmitz classification of clinical grouping, 1, 2, 3 and 4. No. 1 is a very early carcinoma of the cervix; No. 2 is an early carcinoma of the cervix, but still limited to the cervix, as far as clinical findings will reveal; and in No. 3 there is evident extension beyond the cervix into the parametrium, and No. 4 is far advanced cancer of the cervix.

In these days there is an exact measure of the amount of irradiation that may be administered to a given point, in this case the cervix. We may give a certain number of milligram-hours or millicurie-hours, with radium, and then the roentgenologist knows how much irradiation by x-ray he can give to that cervix. It is a formula which involves the measurement of the patient, the distance of the cervix from the tube, and so forth, but we may sum it up by saying that we determine in each case how much irradiation this patient must have.

Inasmuch as radium will apply the irradiation to the cervix in a better manner than the x-ray, in Group 1 we give as much irradiation as possible, 3,600 or 4,000, even more, milligram-hours. Then the roentgenologist has the amount of irradiation that we have given by radium and figures out how much more he can give and not go beyond the total amount that the normal tissues will stand.

In Group 2 we give about the same treatment.

In Group 3, when the cancer has extended into the parametrium, the surrounding tissues of the cervix, it is manifestly beyond the treatment of radium. Radium inserted into the cervix has a therapeutic limit of 3 centimeters, a little over an inch in each direction. Therefore, if we give all of the radium that we can possibly give, we have only reached, therapeutically, a distance of 3 centimeters surrounding the capsule or needle of radium. Therefore, that leaves the extension into the parametrium untreated. This must be reached by deep x-ray therapy.

In these modern days, the Coutard method of giving more x-ray treatments, a larger number with little bit smaller doses, has been a very great advance in the treatment of cancer of the cervix.

The mortality of cancer of the cervix in the better equipped clinics has been improving gradually. This later Coutard multiple, although shorter, individual treatments by the x-ray has added a very great deal to the efficacy of the treatment.

The general opinion, also, is that in cancer of the body of the uterus there should be the operative method of total hysterectomy. In cancer of the body of the uterus, operation is better than irradiation.

However, the older method of making a diagnosis, say, by a frozen section, a diagnostic curettage, and then a hysterectomy at once, has fallen into disfavor because there is a large number of patients who will die of peritonitis when it is done that way. The consensus of opinion now is that, at the time of the diagnostic curettage, if a frozen section shows that there is cancer, then radium is introduced into the uterus for 2,000-3,000 millicurie-hours, and then that will stop or retard the growth of the cancer but, of course, will not cure it. Then wait six weeks and do a hysterectomy.

CHAIRMAN MUSSEY: Dr. Wahlberg:

"In the ordinary home deliveries in town or on the farm, how would you keep the patient quiet long enough to insure proper involution of the uterus?"

DR. E. W. WAHLBERG (Morgan): Postpartum care and rest, again, involve education of the patient. The average patient is willing to coöperate if she knows why she is asked to coöperate, and usually during that quiet hour after the delivery has been performed and you are waiting for possible hemorrhage, I take the father and the attendant aside and tell them the reasons for rest, why we want involution and how it aids in allowing proper healing in episiotomy wounds, and also how it prevents cystoceles, rectoceles, prolapse and other complications.

I leave a printed list of instructions as regards the care of the child and also the care of the mother. This specifically instructs her to lie in bed until the eighth day, let her sit up on the ninth, and let her be up on the tenth. The third day postpartum, I go back for a return call. Again I check up to see whether the instructions are being followed. Then I go through the same explanation with the mother and make her understand the necessity for rest. I haven't had any trouble, provided I explained thoroughly the importance of following directions.

The Apple in the Management of Diarrhea in Children

The Council on Foods reports that the use of fresh apples in the dietary treatment of diarrhea in infants and small children has been much publicized within recent years. Latterly, preparations of dried and powdered apple have been similarly acclaimed. The Council on Foods has considered the available clinical reports. These reports cover practically every kind of diarrhea that is encountered in pediatric practice. The Council concludes that the evidence which is now available indicates that the apple is useful as a therapeutic agent in the dietary management of diarrhea. The mechanism responsible for the reported success of this diet is not clear. Apple powder when suitably prepared is considered a wholesome food and offers a convenient preparation for use in the management of diarrhea of infancy and childhood. It should be emphasized, however, that the use of the fresh or dried apple does not obviate the necessity for other measures, including parenteral administration of fluids when indicated, the careful selection of a suitable transition diet, and competent pediatric supervision. (J.A.M.A., Nov. 13, 1937, p. 1636.)

AN INTRODUCTION TO THE HISTORY OF MEDICINE IN MINNESOTA

By JOHN M. ARMSTRONG
Chairman Historical Committee
Minnesota State Medical Association

A DECADE ago a committee to collect data for a "History of Medicine in Minnesota" was appointed by our State Association. This committee has been active since its establishment and considerable data have been gathered, part of which is in a form suitable for publication. Since various members of the committee have submitted material in a finished form, of necessity there is considerable overlapping, and since it has been difficult to separate subjects which have both a general and local interest and assign them to the proper place, some duplication will occur during the narration.

Since this forms an introduction to future articles which will appear in MINNESOTA MEDICINE, a brief outline of medical history in Minnesota is here presented; later contributions will be more specific as to subject matter.

The history of Minnesota may be roughly divided into five overlapping divisions: exploration, the fur trade, military occupation, the missionary and permanent settlement. Similarly, the medical history may be so divided.

The French explorers and traders came first. Many of them were educated men, among them priests who no doubt were familiar with the medical practice of the age, but we do not find among them men with the title "doctor."

British occupation and the advent of the Northwest Company, a fur trading corporation with headquarters at Montreal, came next. Physicians were employed by this company as part of their organization. They were officially classed as clerks but received additional remuneration for their medical services. These men were stationed at times within the boundaries of our present Minnesota. With the withdrawal of the Northwest Company from American territory in 1816, the American Fur Company took over their posts and form of organization and employed physicians when available.

Military occupation by the United States government took place in 1819 when Fort St. Anthony, now Fort Snelling, was established. With the troops came our first American physician. Since that time one or more medical officers have been stationed there, with the exception of the years 1857-60 when the fort was temporarily abandoned. During the periods when Forts Ridgley and Ripley were occupied, army medical men were also stationed there. Some of these army physicians later attained some eminence both in their profession and in other lines of endeavor.

During the period of military occupancy came the first American missionaries, in 1835. All, no doubt, ministered to the physical as well as to the spiritual needs of the Indian, although but few were physicians.

Following the military occupation came various government expeditions. In those of Long, in 1820, Schoolcraft, in 1832, and David Dale Owen, 1848-50, the scientists accompanying them acted as, or were qualified as, physicians.

Some of them had previously practiced medicine and some later continued the practice of medicine.

The period of settlement began in 1838 with the beginning of lumbering on the St. Croix river, and civilian physicians followed the settlers.

One may say here that the French explorers and traders penetrated Minnesota by three routes along the north shore of Lake Superior, via the Brulé-St. Croix portage and the Green Bay-Wisconsin river route; the British entered by the north shore route; and United States exploration and settlement came in by way of the Mississippi river from the south, except that the troops which established Fort Snelling came by the Green Bay-Wisconsin river. It is logical, then, to find that our civilian physicians, as did our civilian population, followed the tributaries of the Mississippi. Stillwater, St. Paul, St. Anthony, Winona, Wabasha and Taylors Falls were our first towns. Then came Minneapolis, the towns along the Minnesota river, and those on the Mississippi above St. Anthony Falls.

Population grew rapidly during the sixth decade of the nineteenth century and numbers of physicians followed the emigrants; but since at first there was not sufficient practice to support them, many abandoned their profession and went into farming or trade, while others, after a brief sojourn, moved to other parts of the territory. With the opening of the territorial road north from Iowa, emigrants came into southern Minnesota overland, and the towns of Albert Lea, Rochester, Owatonna and Faribault came into being and attracted more medical men. Likewise southwestern Minnesota was peopled via the government road west to Fort Abercrombie. Northwestern Minnesota was not well settled till the railroads entered that region about 1870. Settlement in northeastern Minnesota lagged, as the country was not suitable for agriculture. Here the first settlers came by the lake route.

As soon as there were enough physicians they associated themselves for exchange of ideas and other mutual benefits and our first medical society was organized. This was a territorial organization formed in 1853 and local societies began to be formed soon afterward, though our present societies were not established till some years after the termination of the Civil War.

The earliest literature relating to medicine in our state is to be found in the reports of the government expeditions and reports of army surgeons, which are of considerable interest though few in number.

Medical journalism began in 1870 with the publication of the *Northwestern Medical and Surgical Journal.* Since that time nearly a dozen medical journals have been published, of which but two exist at the present time.

The teaching of medicine, other than the preceptorial system, began as early as 1870 with the establishment of preparatory medical schools in St. Paul and Winona.

Later other schools were incorporated and conferred degrees. At the present time our University and its affiliate, the Mayo Foundation, are the sole teaching institutions.

Our first private hospital opened its doors in 1854 and the first state hospital in 1866.

The State Board of Health was established in 1872, preceded only by those of Massachusetts and California.

The development and progress of legislation pertaining to the practice of medicine and the status of the physician in the community have undergone various changes since the organization of Minnesota as an entity.

All these and other aspects of medicine will receive treatment at length.

Until 1854 our white population was largely composed of native Americans and French Canadians, but at that time emigrants of foreign birth began pouring in and physicians of foreign birth and training followed, giving a cosmopolitan character to our profession which has had a considerable influence on the development of medicine in our state.

In general, the preceding is an epitome, in outline, of the progress and development of medicine in Minnesota. Much interesting material relating to the services of medical men in the Army and Navy from the War of 1812 till the present has also been gathered. Biographical data, often of more than local interest, shedding considerable light on the progress of medicine and individual achievement have also been secured and will be presented separately or with the county narratives.

The committee feels that the difficulties encountered in recording the events of the last century have been much greater than any future investigator may have in recording those of the present. Hence we have confined our efforts largely to the past century.

It is the earnest desire of the committee that medical items of interest, trivial or not, be sent to the chairman. Particularly desired are old minutes of medical meetings, physicians' diaries, addresses, account books and letters. Material of this nature forms the basis of real insight into prevailing conditions as well as the thought and activities of the individual. Historians in general are turning more and more to data of this nature as source material. May we ask your coöperation in aiding us in our attempt to compile a "History of Medicine in Minnesota"?

J. M. Hayes, M.D.
President, Minnesota State Medical Association

President's Message

To the Members of the Minnesota State Medical Association:

I TAKE this opportunity of wishing you all a very Happy New Year.

While I am duly grateful for the honor of being your president for the coming year, I am not unmindful of the fact that I am still only one small unit in a great organization. Whatever the administration does must be done at your bidding. You are all aware that in an organization of this magnitude, it is not the work of one individual or a small group of individuals, but the combined efforts of all members that bring about the desired results.

The problems of the medical profession have been much the same in the past as they are at present and will be in the future.

An era of depression merely magnifies the problems of those who are to be guardians of our principles, and greater efforts must be put forth to stem the tide of outside aggression. Such periods are always opportune for misguided philanthropic individuals and organizations. Improper care of the sick or the crippled child always furnished an arousing appeal to these individuals or organizations.

They all mean well, but unfortunately their information is frequently gained through improper channels. Only through the practicing physician can this information be properly obtained.

Our state and national medical organizations have the proper machinery and equipment necessary for obtaining information in regard to health problems and the care of the sick. Information obtained through other channels is frequently faulty and misleading. Such information put out to the public is bad for all concerned.

Adequate care of the sick should be the primary objective of every medical organization.

What is adequate care of the sick and how it should be administered are questions much discussed today. We know that there has never been a time when the sick were better taken care of than now. We also know that many new and fantastic schemes for improving medical care are not well founded. They are not products of the practical man.

Experience with various methods tried in other countries as well as some in our own, leads us to the conclusion that our old established Medical Guild is as good or better than any other system of medical care yet proposed.

All scientific improvement, all research or special skill of any nature may be encouraged and made use of under this system.

We do not oppose outside assistance where such assistance is necessary, but the care of the sick must always be kept in the hands of the medical profession.

J. M. Hayes, M.D.
President, Minnesota State
Medical Association

Volume 21 JANUARY, 1938 Number 1

History of Medicine in Minnesota

BEGINNING with this issue of MINNESOTA MEDICINE, a number of pages will be devoted each month to the publication of the medical history of our state. The proposal of the Historical Committee of the Minnesota State Medical Association to publish in the journal the interesting material it has gathered on the medical activities in the state up to the year 1900, met with hearty approval. Doubtless the story of the early days will be much more widely read in piecemeal than in volume form. However, it is the present purpose of the committee eventually to publish in book form the pages appearing in MINNESOTA MEDICINE.

History, particularly medical history, has a special fascination for certain members of our profession, but it is our hope that all our readers will enjoy the published history of medicine in our state as it appears in these pages each month.

The "Elixir" of Sulfanilimide Episode

PHYSICIANS have realized for some time that the existing Food and Drugs Act does not sufficiently protect the public. Proprietaries of unknown formula are allowed to be sold directly to the public, a procedure not allowed in certain foreign countries. Opposition, however, on the part of proprietary manufacturers has been so strong that remedial legislation has been obstructed. Doubtless a certain amount of prescribing of proprietaries of unknown composition takes place although this is a drop in the bucket compared to the counter sale of these remedies. Occasionally new drugs like dinitrophenol, cinchophen and amidopyrine are offered to the profession before their dangerous qualities are realized. Rarely, fortunately, is a distinctly poisonous drug offered for general distribution.

The tragedy of seventy-three known and twenty more presumptive deaths from the dispensing of Elixir of Sulfanilimide-Massengill, serves to call attention to the inadequacy of the present laws governing the sale of drugs. The so-called elixir was not an elixir in that it contained no alcohol. Further, the elixir contained an undeclared solvent—diethylene glycol—which proved to be the fatal poison. It seems, too, that the poisonous quality of diethylene glycol should have been known to the manufacturing chemist. And finally, although this was a new preparation, no preliminary tests as to its poisonous nature were made before it was sold to the drug trade.

We are told the only law violated was the use of the term "elixir" for a preparation which was not an elixir. Had the law required the revelation of the presence of the relatively unknown diethylene glycol as a solvent it is problematic how many of those physicians who prescribed the preparation would have

been deterred, so great is the faith of most physicians in the pharmaceutical houses. While these concerns are jealous of their reputations and as a rule are careful not to introduce drugs harmful in the recommended dosage, there is no law requiring such precaution.

Corrective legislation has been presented to Congress by Senator Copeland embodying the recommendations of the Secretary of Agriculture, who investigated the tragedy. In brief his recommendations were:

1. "License control of new drugs to insure that they will not be generally distributed until experimental and clinical tests have shown them to be safe for use." This is not to prevent the development of new drugs by experimentation in competent hands.

2. "Prohibition of drugs which are dangerous to health when administered in accordance with the manufacturers' direction for use." We presume this means the prohibition of direct sale to the public of such drugs.

3. "Requirement that drug labels bear appropriate directions for use and warning against probable misuse." Such warnings are certainly indicated in the case of dinitrophenol, cinchophen and amidopyrine, and their direct sale to the public should be prohibited.

4. "Prohibition of secret remedies by requiring that labels disclose fully the composition of drugs." Vigorous opposition to this proposal on the part of the proprietary manufacturers may be expected.

This proposed legislation will be lacking if it does not include the prohibition of direct sale to the public not only of distinctly dangerous drugs which should be limited to dispensation by prescription, but also of drugs which are habit-forming, including the barbiturates, the continued use of which in certain cases results in mental changes. The proposed changes, along with heavier penalties for infringement, will add protection to the public, but too much emphasis cannot be placed on the importance of each physician's prescribing only those remedies about which he is informed.

Health Progress

IT must be a matter of satisfaction to everyone associated with public health activities to know that the health of our citizens as reflected by mortality statistics has shown a marked improvement in recent years. A volume recently published* by the Metropolitan Life Insurance Company presents an analysis of the company's mortality experience for the twenty-five years from 1911 to 1935 inclusive, and the expert interpretation of its mortality experience over this period supplies a confirmation of impressions and some facts which may be new to many.

The mortality experience of this large company corresponds very closely to that of the registration area of the United States and serves as a check on government figures. During the twenty-five year period reviewed the life expectancy of the American citizen has been increased from 46.63 to 60.25 years, an increase of 30 per cent. This has resulted in spite of a World War, a most severe influenza epidemic and one of the worst economic depressions this country has experienced. Most of this increase in life expectancy has been due to the marked reduction in the diseases afflicting youth, childhood and particularly infancy.

The trend of the mortality curve for this twenty-five year period has been downward almost constantly except during the influenza epidemic, and, strange to say, has been particularly marked the last five years in spite of the economic depression. This does not suggest that the people are suffering from lack of medical care.

It may not be generally realized that the mortality in the first four years of life is comparatively high, showing a marked drop in the next four years of life until it is lowest during the ages of ten to fourteen. The curve then rises until at the age period of thirty-five to forty-four it is nearly double that of the first four years of life and, of course, is highest beyond the age of sixty-five. For all ages combined the mortality of males is 30 per cent higher than for females, and for the colored population is much greater than for the whites.

The reduction in incidence and mortality from

*Dublin, Louis I. and Lotka, Alfred J.: Twenty-five Years of Health Progress: A Study of the Mortality Experience Among Industrial Policyholders of the Metropolitan Life Insurance Company, 1911 to 1935. New York: Metropolitan Life Insurance Company, 1937.

the contagious diseases of childhood is particularly gratifying. Diphtheria heads the list with the most marked mortality reduction. Antitoxin and widespread immunization explains this but does not explain the marked reduction for measles, whooping cough and scarlet fever. Physicians may note that diphtheria rarely occurs in the first year of life in contrast to whooping cough and measles. The pre-school age, however, is an important period for immunization against diphtheria. The mortality for measles and its complications is greatest in the first and second years of life and the same applies to whooping cough, which in these two years of life accounts for nearly three times as many deaths as measles, scarlet fever and diphtheria combined.

Tuberculosis, though still the leading cause of death in early adult life exacts only a third the toll it did twenty-five years ago. Males die of the disease in greater numbers over the age of forty-five, while the age period of twenty to twenty-five is the worst for females. In recent years, the rate for girls ten to twenty years of age is twice that for boys, while at forty-five to fifty-five the rate for males is three and a half times that for females.

The necessary grouping of influenza and pneumonia makes deductions somewhat difficult. Some 450,000 to 600,000 deaths occurred in our population from these causes during the epidemic, and it is estimated some six to ten million throughout the world, more than from military operations throughout the World War.

We have known that lobar pneumonia is comparatively mild in Minnesota. In certain states, it is milder than in Minnesota, but is considerably more malignant in most of the Atlantic seaboard states, Missouri, Tennessee and Kentucky, and most severe in New Mexico, Arizona, and Nevada. There has been a decided decline in mortality from this disease during the past five years, for which pneumococcic serum may be partly responsible.

The increase in cancer deaths has been about 14.5 per cent. Several factors doubtless account for this. Better diagnosis and more autopsies revealing hidden cancer undoubtedly play a part. The shift of cancer mortality from seventh to second place during this period is due, however, for the most part to the reduction in other diseases.

The cardiovascular-renal group heads the list and accounts for about a third of all deaths; at the age of forty-five almost half. Infection as well as the aging process plays a part in the causation of these diseases. Even in this group there has been a slight fall in the death rate although this has been due to an improvement in youth where infections such as rheumatic fever and scarlet fever are more often causative factors. While valvular heart disease has fallen to half the mortality of fifteen years ago, this has been for the most part in those under twenty-five years of age. Heart muscle disease, however, has shown a marked increase at each age period and especially after the age of forty-five. The reporting of coronary diseases has changed considerably in recent years and the doubling of reported deaths from this cause in the past five years must be interpreted with caution although most students of the question believe there has been a definite increase in coronary disease, the most common cause of which is hypertension.

In spite of the discovery of insulin in 1922 the mortality from diabetes has increased, especially in women in whom it is now almost twice that of men. The benefits of insulin are seen particularly in diabetes in youth. The increase is attributed to more frequent diagnosis, the greater percentage of the population now in the older age groups and the increase in Jewish population from one million to four million in the past thirty years. Overweight and overindulgence in food and drink along with less manual work all play their part.

In spite of scientific advance in diagnosis and treatment, the figures for the puerperal state and appendicitis show no improvement during this period. An appreciable percentage of such deaths are preventable, and concentration on lay and professional education should produce results.

The story of accidental deaths in our country is appalling. In 1934, more than 100,000 persons were killed in accidents of one kind or another. In Canada the rate is 40 per cent less. We are surprised to learn that the trend during the twenty-five year period among policyholders has been downward and in the closing five years of the period was 25 per cent less than during the first five years. About a quarter of the fatal

accidents occurred at home and another quarter were due to automobile accidents.

The rise in the number of automobile accidents from 2,100 in 1911 to 34,000 in 1934 is disgraceful and indicates the marked improvement which must have taken place in the occurrence of other accidents. Something will have to be done about it, but the solution is not clear.

The remarkable improvement in public health during the past twenty-five years should be a source of satisfaction to all these agencies devoted to health activities. The analysis of mortality statistics presented in this volume indicates where the attack should be made by medical as well as other agencies to increase life expectancy further.

MEDICAL BROADCAST FOR JANUARY

The Minnesota State Medical Association Morning Health Service.

The Minnesota State Medical Association broadcasts weekly at 9:45 o'clock every Saturday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

January 1—Public Health Objectives
January 8—Pneumonia Types
January 15—Measles Prevention
January 22—Early Tuberculosis
January 29—Preventive Dentistry

Vaccines in Colds

All investigations to date have consistently shown a wide variety of bacteria present in colds. This fact necessitates the assumption either that colds are not due to any specific organism but that symptoms which we recognize by that term can be produced by a large number of different bacteria, or that the specific cause has not yet been identified. It is evident, therefore, that that any attempt made now to produce immunity by vaccines must be aimed at a combination of organisms, with the hope of chance inclusion of the right one, or that the combination also by accident contains the as yet unidentified principle which causes all colds. Neither of these possibilities seems to offer a scientifically rational approach to prophylaxis. The duration of acquired immunity is another important question. There is no real scientific evidence supporting the use of vaccines for the common cold. In those individual instances in which benefit seems to result, this apparent effect may be due either to the individual fluctuation in frequency which is generally observed or to some nonspecific stimulation of immunity created by the administered proteins. (J. A. M. A., Oct. 9, 1937, p. 1217.)

In Memoriam

Warren Wilson
1863-1937

DR. Warren Wilson, long identified with civic and professional interests in Northfield, died September 4, 1937, from coronary thrombosis.

Dr. Wilson was born at Lyndoch, Ontario, April 24, 1863. He attended local grade schools and the high school at Simcoe and took his pre-medical course at Western University, London, Ontario. He received his medical degree at Northwestern University in 1889.

After practicing a year at Belding, Michigan, and several years at Duluth, Dr. Wilson bought the practice of Dr. S. J. Schmidt in Northfield. During the World War he headed the medical service of the S.A.T.C. at Carleton and St. Olaf with the rank of Lieutenant. In 1919 he was joined in practice by Dr. Joseph Moses and in 1924 by his son, Dr. Warren E. Wilson. In 1930, because of his health, he retired from active practice but was available for consultation.

In 1895 Dr. Wilson married Ruby Evans of Duluth. Her death occurred in 1897. In 1898 he married Bertha Schmidt who survives him. He is also survived by two sons, Dr. Warren E. Wilson of Northfield and Paul S. Wilson, who is superintendent of schools at Glencoe. A sister and three brothers reside in Ontario.

Dr. Wilson drew the plans and assisted in the management of the hospital established at Northfield by the Odd Fellows of Minnesota. Ten years later he took a leading part in the establishment of the hospital built by the Northfield Hospital Association. This hospital was eventually turned over to the city. Dr. Wilson was also a member of the Board of Education of Northfield for ten years. An active Mason, he planned the present Masonic lodge quarters at Northfield.

Dr. Wilson was an ardent golfer and became much interested in woodcraft in his later years. In his passing Northfield has lost a valuable citizen, a man of sound character and outstanding achievement.

Cobra Venom in Arthritis

For a number of years various venoms, especially those of bees and snakes, have been used in the treatment of a variety of diseases. Of commercial preparations of different venoms, those of bees have been most widely used. No extensive scientific study has been made concerning the value of cobra (or bee) toxins in chronic arthritis. Many believe that such relief as arthritis patients may obtain from bee or snake venoms is probably derived from a reaction somewhat similar to that from foreign proteins (milk, typhoid vaccine). The value of snake venom as a superior coagulant is more definitely established. (J. A. M. A., Oct. 2, 1937, p. 1143.)

The Council Meets

THE following resolution was passed by the Council in connection with acceptance by the Council of the 1938 budget presented by Dr. H. Z. Giffin, Rochester, chairman of the Finance Committee of the Council:

"Doctor Meyerding has been on leave of absence, without salary, as to active executive duties since September 1, 1937. Mr. Rosell has been assuming responsibility under the direction of the Finance Committee for office administration and management except as to bookkeeping, receipt of mail, and custody of important documents, which have continued as under the previous regime. Bonds are required for those assuming such duties.

"The Finance Committee, in coöperation with Doctor Meyerding, has arranged for the transference of responsibility for the bookkeeping system, the custody of important documents, the opening of all mail, except that with Doctor Meyerding's name on it, and all other activities to Mr. Rosell. It has been suggested that proper bonding and other safeguards such as insurance, as well as transfer of bookkeeping, shall be completed before January 1, 1938. The books have been reviewed as of August 31, 1937, and found to be correct.

"The Council, in confirming this transfer of office management, offers the following resolution to be spread upon the minutes:

"The advantage of the past coöperation between the Minnesota Public Health Association and the Minnesota State Medical Association is fully recognized, and it is desirable that the coöperation continue as far as possible.

"The valuable services of Doctor Meyerding over a period of thirteen years in his capacity as active secretary of the Minnesota State Medical Association are appreciated by all and especially by those who best know of the struggles of the past thirteen years which have placed Minnesota medicine in its present high ranking.

"Our Association has grown and developed in many directions during Doctor Meyerding's administration. Outstanding among his services are: the growth of our membership; committee activities; development of the component society; the interesting of the county medical group in local medical relief and welfare; county contact committees; administration of finance; the public health education program; the medical economics education program; and the growth of the annual meeting with its scientific and technical exhibits. More important than all of these is our present close and friendly relationship with all large official and voluntary agencies and associations of the State.

"There never was a time when unity of thought and action on the part of all interested in public welfare and the advancement of medicine was more necessary than it is now. It is the desire and hope of the Council that Doctor Meyerding, although not responsible as to active duties, should be freely consulted regarding policies affecting the practice of medicine. We deeply appreciate the fact that he has volunteered such aid."

Thanks of the Council were extended to Doctor Giffin and members of his committee for their work.

Ready to Publish

Only a small amount of work remains to be done to complete the "History of Medicine in Minnesota" as it has been planned by the Historical Committee.

The date 1900 was chosen arbitrarily by the committee as the ending point for the history. In view of the impossibility of tracing the history of every society in the state, the committee has followed the early lines of transportation and will cover most of the settlements where pioneer medical men established themselves.

The compilation represents much devoted research on the part of members of the committee and others who have assisted them. It was close to the heart of the late Dr. H. M. Workman, for many years chairman of the Council, and it has been a major interest of Dr. Arthur S. Hamilton of Minneapolis, previous chairman, who was forced by illness to relinquish the

work, also to the present chairman, Dr. John M. Armstrong of St. Paul.

Doctor Armstrong reported upon the progress of the work, and the Council voted unanimously to publish it serially, under the editorship of Doctor Armstrong, in MINNESOTA MEDICINE.

The Council also voted an expression of appreciation for the work of Doctor Armstrong and his associates.

Care for Work Camps

The Treasury Department has asked for bids for regular sanitary inspection and medical care in the work camps of the Resettlement Administration in Northern Minnesota. Some of these camps are at some distance from resident doctors and require considerable time of the attending physician.

It is recognized that procedure for care of these camps is dictated from Washington and must be followed. The Council suggested, however, that the county societies involved make an arrangement as societies with the camp administration in St. Paul to do the work. County society members, in turn, could assign the job to the man or men nearest the camp and make mutually agreeable division or assignment of the funds.

In general, this is the scheme known as the "Iowa Plan," used first to handle care for the indigent, but well adapted, also, for special work such as care for the men in the work camps. The object, of course, is to avoid objectionable competitive bidding on contracts for medical work.

Interprofessional Meetings

Interprofessional meetings in each county and district society were approved by the Council at this meeting. These meetings are being suggested by the Interprofessional Relationship Committee of the state association, of which Dr. F. J. Savage is chairman. They are to be informal gatherings at which representatives of all the professions get together, become acquainted with mutual problems, unite for better community action on health problems. A yearly public health meeting sponsored by the entire interprofessional group is a further suggestion of the committee which met with Council approval.

These gatherings should be kept informal and without regular constitution or elected officers, in the opinion of Council and committee, since organizations thus formed are sometimes used by participating groups for purposes not contemplated by the founders.

A letter detailing the aims and purposes of these meetings has been sent to all secretaires by the Interprofessional Committee.

County Officers' Meeting

The 1938 County Officers' Conference of the State Association will be held Saturday, February 26, at the Saint Paul Hotel, Saint Paul. The date was approved by the Council and a request has subsequently been sent to all secretaries by Executive Secretary R. R. Rosell, for suggestions as to subjects that will be of most value at this meeting.

Survey in California

The California survey of sickness and sickness costs is complete at last and available to students of the subject.

This survey covers the years 1934-1935 and cost the California State Medical Association $50,000, the Federal government approximately $55,000, the California Dental Society $800, the whole making a grand total of $102,352.66.

The studies cover the medical vicissitudes of 60,033 persons out of a population of more than 5,000,000. Subject to inquiry was the general character of the population, its income, its morbidity, the medical facilities available, the extent to which they are utilized, likewise the extent to which the cost might have been instrumental in curtailing their use.

Out of the 60,003, a group of 8,260 were discovered who were in need of medical care. Of these, 4,810 were receiving care at the time of the interview, leaving 3,459, or 5.7 per cent, presumably in need of care which they were not receiving. Not a very large percentage, surely, when you consider that some of the 5.7 per cent undoubtedly did not desire medical care whether they needed it or not.

There are, in California, some 9,000 physicians licensed to practice medicine; also, 1,403 osteopaths, 2,500 chiropractors, 255 drugless

therapists, 39 neuropaths and 2,000 Christian Science practitioners.

This is undoubtedly the most complete survey of its kind ever made in America. Whether it throws sufficient light on a tangled situation to repay the huge expenditure is a matter of opinion. It should be of great interest, however, to all who are concerned in the economic problems of medicine. Copies may be obtained from the office of the California State Medical Association, 450 Sutter Street, San Francisco, for $2.00.

Syphilis Campaign

The widespread campaign of publicity about venereal disease brings with it definite problems to physicians.

There is no doubt as to the worth and advisability of accurate knowledge about these diseases on the part of the public in general and the worth of routine use of the diagnostic measures.

A wave of popular enthusiasm about any health campaign carries with it possibilities of danger, however.

Lay organizers, quacks, ill-advised enthusiasts are likely to take advantage of it.

The *Journal of the American Medical Association* reports a commercial organization in Los Angeles organized to get money out of restaurants and food handling establishments in exchange for window signs to indicate that employees are free from venereal disease. Decidedly sketchy and unreliable means of vouching for the condition of employees were arranged by this company.

Doctors Must Assist

In Minnesota, the Junior Chamber of Commerce desires to make venereal disease education a major welfare project for the year. It is obvious, of course, that the Junior Chamber is incapable of carrying on any such campaign without assistance. Also it is obvious that the county medical society in every center where such a campaign is started should be the medical agency to direct and assist with the campaign. If the county medical society fails of this duty there are other agencies and individuals that will jump at the chance.

Saint Paul Project

In Saint Paul the Junior Chamber of Commerce was assisted by the Ramsey County Medical Society, with the result that every school, college, luncheon club and many other organized groups were reached by a qualified and especially trained representative of the medical society.

In Pennsylvania a state-wide educational campaign is now in progress under the auspices of the medical association committee. In the course of the campaign free Wassermann tests will be offered to all comers.

Free Tests

Free tests have been considered, also, in one of the Minnesota towns where the Junior Chamber wishes to stage a campaign. The question of whether or not free diagnostic tests should be a feature depends upon the local county medical society. If members approve and are willing to do the work in the name of the county society there can be no more objection to these tests than to other special types of public health work done by medical societies as a unit, for the period of a campaign.

Minnesota is in far better position than many other states to undertake a widespread educational campaign to bring in untreated persons for treatment as well as to extend use of the test as a routine part of every medical examination. The venereal disease program of the State Board of Health has steadily maintained laboratory service for diagnostic tests and provided drugs for those unable to pay for them for many years. There are facilities for the diagnosis and care of the disease in all parts of the state.

Handicapped

Sir Henry Brackenbury, chairman of the council of the British Medical Association, believes that a health insurance plan such as exists in England, Scotland and Wales would be enormously handicapped in the United States.

In the course of informal remarks during a recent visit to this country, Sir Henry made some interesting observations on the subject. They gain significance when it is recalled that he is an often-quoted authority on the English

system and that he has had much to do with establishment of England's rates and rules.

Sir Henry says that whatever success the English system has had is due to the homogeneity of race in England, Scotland and Wales and the likeness of the background of all their peoples. Also to the homogeneity in race-type, general professional training and outlook of their physicians. He attributes its workability, also, to the existence in Britain of a permanent civil service personnel possessed of continuous and definite authority to carry out the law, no matter what political group names the nominal heads of departments.

In the United States the difference in standards and backgrounds of the people, the differences in education and licensure of physicians from state to state and the inevitability of political control in any conceivable plan for compulsory health insurance would provide serious obstacles to success.

"1938 What"

(Monthly Editorial Prepared by the Medical Advisory Committee)

"Thank you for your interest and help in my case. I appreciate the support of the State Association more than I can say."

The above is a part of a recent letter received by your Medical Advisory Committee from one of the State Association's members following the dismissal of his case.

Only one who has gone through the ordeal of anxiously waiting for the time of trial, torn between a feeling of guilt and innocence of wrongdoing, can appreciate the sense of relief felt by the man who penned these words. His was the prayer of thanks, his the evidence of applied friendship.

Could every man, each member of the Association, step into his place and feeling, we should have an Association cemented together by the common ties of mutual interest such as nothing else could do.

There can be no middle road in 1938 in dealing with the unwarranted malpractice case. If the case is one of clear responsibility on the part of physician or surgeon, the aggrieved party should be settled with. If the case is one of the usual type, purely a money-making scheme, it should be fought through all courts. Remember that, in your committee's experience, one illegitimate case settled means at least two more will be brought in the same community within a short time.

The time is now ripe to apply that familiar phrase, "All for one and one for all." Let's make the new year a year of renewed friendships, forgotten disagreements, and forgiven quarrels. We will need patience, perseverance, endurance, and clear, concise, mutual understanding with the many problems that now beset medical practice and our Association's welfare.

Pepys in Minnesota

November 12.—More merciless days of dredging through masses of writings and what not and more than ever attracted by "Assignment in Utopia," in which Eugene Lyons tells of seven years in Russia. So now in Saint Paul, where some hundreds of doctors have feted Meyerding. At breakfast came editors of the press and then interviewers and photographers, and then to speak to the Christmas seal workers, and after that to the Junior Chamber of Commerce to speak on syphilis; and old Pepys reminded them that we must look for syphilis not only in the Junior Chamber but also in the Junior League. Next with Ben Wright to Minneapolis to speak on the radio, and after that to the annual dinner of the health association. Now here came Myers and Slater and many more, and a town crier rang out the call and an a cappella choir (no accompaniment, thank you) sang merrily. So old Pepys talked some more and a local medico came up to Mistress Pepys and said: "Your father made a swell speech"; so old Pepys decided to begin dieting again.

November 13.—At 7:30 to breakfast with the officers and council of the state medical society, talked of this and that and speaking of planning heard Chesley tell of the man in Maine where the fog was so thick that when he went up to shingle the roof and the fog cleared suddenly, he fell in the manure pile because he had shingled out ten feet from the barn onto the fog. And Adson spoke well and also Light, and then all went to see Minnesota perform against Northwestern 7 to 0; so now I get my $5.00 back. At night driving to Rochester in a blinding snow and an airplane is safer.—From Tonics and Sedatives, Pepys' Diary, *Journal of the American Medical Association,* November 27.

Illegal

Acting Comptroller-General Elliott has declared the medical plan of the Homeowners' Loan Corporation illegal. This HOLC plan provides group sickness insurance for its employees and it was financed by $40,000 of Federal funds.

In view of the special status of the HOLC the opinion of the Comptroller-General must be viewed as purely advisory. There is no specific prohibition by Congress for the action and, in any case, the money is already spent.

Minnesota State Board of Medical Examiners

Worthington Osteopath Fined $250.00 and Costs For Unlawful Practice of Medicine

State of Minnesota *vs.* Dunn.

On November 30, 1937, Donald J. Dunn, forty-five years of age, entered a plea of guilty to an information charging him with practicing medicine without a license. Dunn, who holds a license to practice osteopathy, but not medicine, and who maintains an office at Worthington, Minnesota, was sentenced by the Honorable Charles A. Flinn, Judge of the District Court, to pay a fine of $250.00 plus the court costs, or serve four months in the Nobles County Jail. Dunn paid the fine plus court costs of $6.90, or a total of $256.90.

The Minnesota State Board of Medical Examiners had received a number of complaints that the defendant was injecting medicine and furnishing medicine to be taken internally. The investigation disclosed that Dunn had written a number of prescriptions to be taken internally, but that he had neither written the name of the patient upon the prescriptions, nor had he signed them. The particular case upon which a complaint was filed concerned a young man who stated that he consulted the defendant and had been advised that he was in a run down condition and suffering from an inflammation of the kidneys and the bladder. He stated that the defendant gave him a number of hypodermic injections in the arm and some pills to be taken internally. He stated that he also received a bottle of so-called blood medicine to be taken internally and a written prescription for a second bottle of the same medicine. He stated that he received a bill from the defendant in the sum of $162.00. The patient stated that he did not get any better and, upon consulting a physician, was advised that he was suffering from a different condition from that stated by the defendant. He also stated that he has made considerable improvement since being under medical care.

The osteopathic law of Minnesota specifically provides that the practice of osteopathy

"is hereby declared distinct from that of medicine or surgery * * * Osteopathic physicians, when duly licensed, shall have the right to practice osteopathy * * * including the use and administration in connection with the practice of obstetrics, minor surgery and toxicology only of anesthetics, narcotics, antidotes and antiseptics."

The law also provides:

"Except as hereinbefore expressly authorized as to the administration of anesthetics, narcotics, antidotes and the use of antiseptics, the license shall not authorize the holder to give or prescribe drugs for internal use."

—Section 5736-5737, Mason's Minnesota Statutes for 1927.

Itasca County Practitioner Pleads Guilty

Re: State of Minnesota *vs.* Smith

On December 10, 1937, Christopher Columbus Smith, seventy-seven years of age, entered a plea of guilty to an information charging him with practicing healing without a basic science certificate. Smith entered his plea of guilty before the Honorable Graham M. Torrance, Judge of the District Court at Aitkin, Minnesota. After hearing the facts, Judge Torrance sentenced Smith to a term of four months in the Itasca County Jail, and placed him on probation until September 13, 1938, on a number of conditions, two of which are that Smith absolutely refrain from practicing medicine in any manner, or from holding himself out to the public as a physician.

Smith moved into northern Itasca County in 1920, and resided on a farm about a mile east of Effie. In 1930 he was given a warning by the State Board of Medical Examiners to refrain from practicing medicine, and he stated, at that time, that if given an opportunity he would return to the State of Texas. However, he did not leave and in 1933, following a fire, he moved into Effie, where he built a small place and has continued to practice medicine until the time of his arrest on December 9, 1937. Smith stated to the Court that he was born in Fannin County, Texas, and raised in Davis County, Missouri. He stated that he attended the old Medical School at Keokuk, Iowa, graduating in 1885, and being licensed by the Iowa State Board of Medical Examiners in 1886, holding license number 1050. He also stated that he had never been convicted of a crime. Judge Torrance warned the defendant that under no circumstances could he be permitted to practice medicine. It was stated to the Court that the sanitary conditions at Smith's residence, where he maintained his office, were very bad.

The State Board of Medical Examiners wishes to acknowledge the fine coöperation of John J. Benton, County Attorney, and Sheriff Elmer Madson.

List of Physicians Licensed by The Minnesota State Board of Medical Examiners, November 12, 1937

By Examination

Name	School	Address
Arkin, Archie Abraham,	U. of Manitoba, M.D., 1932,	Minneapolis, Minn.
Beizer, Lawrence,	Harvard U., M.D., 1934,	Rochester, Minn.
Bellis, Carroll Joseph,	U. of Minn., M.B. and M.D., 1936,	Minneapolis, Minn.
Benesh, Louis Alfred,	U. of Minn., M.B., 1937,	Minneapolis, Minn.
Benkwitz, Karl Burton,	U. of Rochester, M.D., 1934,	Minneapolis, Minn.
Bennett, Robert Leo, Jr.,	U. of Pittsburgh, M.D., 1936,	Rochester, Minn.
Berlin, Anthony Salvatore,	U. of Minn., M.B. and M.D., 1937,	St. Paul, Minn.
Black, Benjamin Marden,	Stanford U., M.D., 1936,	Rochester, Minn.
Black, John Robert,	McGill U., M.D., 1934,	Rochester, Minn.
Boysen, John Edward,	U. of Minn., M.B., 1936; M.D., 1937,	Pelican Rapids, Minn.
Brown, Henry Allen,	Med. Col. of Va., M.D., 1934,	Rochester, Minn.
Browne, Harry C., Jr.,	U. of Ore., M.D., 1935,	Rochester, Minn.
Brumm, Harold J.,	Rush Med. Col., M.D., 1936,	Rochester, Minn.
Cabell, Charles Lorraine,	U. of Va., M.D., 1934,	Rochester, Minn.
Cameron, David Molloy,	U. of Texas, M.D., 1935,	Rochester, Minn.
Conway, John Francis,	U. of Rochester, M.D., 1935,	Rochester, Minn.
Cottrell, Lillian,	U. of Colo., M.D., 1936,	Minneapolis, Minn.
Cowan, Donald William,	U. of Minn, M.B., and M.D., 1931,	Minneapolis, Minn.
Craft, Charles Brigman,	Tulane U., M.D., 1935,	Minneapolis, Minn.
Davies, Roberts Judson,	U. of Minn., M.B., 1933; M.D., 1934,	Nopeming, Minn.
Dees, Myrta Susan Coons,	Johns Hopkins, M.D., 1934,	Minneapolis, Minn.

Delmonico, E. Joseph, Syracuse U., M.D., 1930, Rochester, Minn.
Dublin, William Brooks, U. of Cal., M.D., 1936; Rochester, Minn.
Engle, David Edwin, Indiana U., M.D., 1934, Rochester, Minn.
Foster, Furman Lamar, U. of Minn., M.B., 1936; M.D., 1937, Minneapolis, Minn.
Freedman, Harold Charles, U. of Minn., M.B., 1937, Minneapolis, Minn.
Freeman, William Neil, U. of Chicago, M.D., 1937, St. Cloud, Minn.
Goodson, William Hammack, Jr., Harvard U., M.D., 1934, Rochester, Minn.
Grindlay, John Happer, Harvard U., M.D., 1935, Rochester, Minn.
Grove, M. Stuart, U. of Minn., M.B., 1934; M.D., 1935, St. Paul, Minn.
Hammer, Howard John, Wayne U., M.B., 1934; M.D., 1935, Rochester, Minn.
Heise, William von Rohr, Northwestern, M.B., 1934; M.D., 1935, Winona, Minn.
Hildebrand, Alice Grace, U. of Neb., M.D., 1936, Rochester, Minn.
Judd, Edward Starr, Jr., Rush Med. Col., M.D., 1937, Rochester, Minn.
Kernan, Phillip Donald, U. of Wis., M.D., 1933, Minneapolis, Minn.
Kimmel, George Charles, Jr., U. of Minn., M.B., 1936; M.D., 1937, Minneapolis, Minn.
Koch, Eleanor Alice Steele, Johns Hopkins, M.D., 1934, Rochester, Minn.
Lange, Elizabeth Greason Hunter, U. of Mich., M.D., 1928, Minneapolis, Minn.
Leighton, Robert Sisson, II, U. of Minn., M.B., 1937, Minneapolis, Minn.
Madding, Gordon Francis, Northwestern, M.B., 1936; M.D., 1937, Rochester, Minn.
Mitchell, Mancel Talcott, U. of Minn., M.B., 1934; M.D., 1935, Minneapolis, Minn.
Muir, Walter Francis, U. of Minn., M.B. and M.D., 1937, Graceville, Minn.
O'Brien, Louis Timothy, U. of Minn., M.B., 1935; M.D., 1936, Wahpeton, N. Dak.
Olds, John Whitney, Rush Med. Col., M.D., 1936, Rochester, Minn.
Pearman, Robert Oliver Davidson, Harvard U., M.D., 1935, Rochester, Minn.
Peters, Stanley Bruce, U. of Rochester, M.D., 1935, Virginia, Minn.
Ralph, Robert Douglas, Queens U., M.D., 1932, Rochester, Minn.
Schiele, Burtrum Clarence, U. of Colo., M.D., 1931, Minneapolis, Minn.
Schmitz, Anthony A., U. of Minn., M.B., 1937, Minneapolis, Minn.
Schneider, Herbert Hoyt, U. of Kansas, M.D., 1936, Rochester, Minn.
Seedorf, Everett Emil, U. of Wis., M.D., 1936, Rochester, Minn.
Seldon, Thomas Harry, Queens U., M.D., 1929, Rochester, Minn.
Skinner, Ira Clifton, Jr., Tulane U., M.D., 1935, Rochester, Minn.
Smith, Baxter Allen, Jr., U. of Minn., M.B., 1936; M.D., 1937, Minneapolis, Minn.
Spink, Wesley William, Harvard U., M.D., 1932, Minneapolis, Minn.
Sturley, Rodney Francis, U. of Minn., M.B., 1937, Minneapolis, Minn.
Swartz, Frederick Charles, U. of Cincinnati, M.B., 1931; M.D., 1932, Rochester, Minn.
Templin, David Browning, U. of Chicago, M.D., 1937, Rochester, Minn.
Thomas, Margaret Jane, U. of Minn., M.B., 1936; M.D., 1937, Minneapolis, Minn.
Trach, Benedict, U. of Minn., M.B., 1937, Chicago, Ill.
Trueman, Kenneth Rankine, U. of Manitoba, M.D., 1934, Rochester, Minn.
Vickers, Paul Merton, U. of Minn., M.B., 1936; M.D., 1937, Rochester, Minn.
Waisman, Morris, U. of Ill., M.D., 1936, Rochester, Minn.
Watterson, Kenneth Ward, U. of Pittsburgh, M.D., 1929, Rochester, Minn.
Wellman, Thomas Gibbs, U. of Minn., M.B. and M.D., 1937, Lake City, Minn.
Wollaeger, Eric Edwin, Harvard U., M.D., 1934, Rochester, Minn.

By Reciprocity

Dix, Christopher Robert, U. of Wis., M.D., 1935, Rochester, Minn.
MacKay, Alexander Russell, Northwestern, M.D., 1936, Rochester, Minn.
Walsh, John Joseph, Jefferson, M.D., 1935, Rochester, Minn.
Rosenbladt, Louis Mayo, U. of Nebr., M.D., 1932, St. Paul, Minn.
Langmack, William August, Marquette U., M.D., 1936, Cloquet, Minn.
Leland, John Augustin Charles, Jr., Jefferson Med. Col., M.D., 1936, Minneapolis, Minn.
Soniat, Theodore Louis Lucian, Tulane U., M.D., 1935, Rochester, Minn.

National Board Credentials

Hartwell, Donald Clifford, Col. of Med. Evang., M.D., 1937, Wayzata, Minn.
Harris, William Elsworth Stanley, U. of Minn., M.B., 1936; M.D., 1937, St. Paul, Minn.
Pratt, Sidney Charles, U. of Minn., M.B., 1936; M.D., 1937, Minneapolis, Minn.
Sather, George Allen, Rush Med. Col., M.D., 1937, Fosston, Minn.

If you haven't sent in your Christmas Seal money, do so now!

OF GENERAL INTEREST

Dr. Albert Goblirsch of Faribault was recently married to Miss Dorothy Fraser of Minneapolis.

* * *

Dr. M. J. Lindahl of Pipestone has moved to Sherburn, where he will practice medicine.

* * *

Dr. W. B. Beadie of Cannon Falls conducted a chest clinic early in December.

* * *

Dr. S. A. Whitson of Alden is taking postgraduate work in major surgery at the Cook County Hospital, Chicago.

* * *

Dr. Ralph E. Moyer of Minneapolis has recently been appointed to the staff at the Minnesota State School and Colony in Faribault.

* * *

Dr. Edmund V. Pellettiere of Thief River Falls was recently married in New Orleans. Dr. and Mrs. Pellettiere are now at home in Thief River Falls.

* * *

Dr. John A. Tweedy has become affiliated with his father, Dr. G. J. Tweedy, and his brother, Dr. R. B. Tweedy, of Winona, in the practice of medicine.

* * *

Dr. J. C. Masson and Dr. A. W. Adson of Rochester left early in December for a three-weeks' fishing and hunting trip in Texas and New Mexico.

* * *

A number of Willmar physicians and their wives were recently entertained by the nurses of the Rice Memorial Hospital at a housewarming for the nurses' home next to the hospital.

* * *

Dr. F. E. Harrington, Commissioner of Public Health in Minneapolis, began a new series of health talks over KSTP on December 22, at 11:15 A.M. The program is being sponsored by the Glenwood-Inglewood Pure Spring Water Company.

* * *

Dr. and Mrs. F. U. Davis of Faribault started early in December on an extended trip throughout the southern states, Mexico and California. They are traveling in their modern and well equipped house trailer. They expect to return to Faribault in the spring.

February 2, 1938, has been designated as National Social Hygiene Day by the American Social Hygiene Association for the purpose of eliciting interest in the various activities directed against venereal disease.

The Association, with headquarters at 50 West 50th Street, New York City, will supply interested persons or groups with suggestions for meetings and materials such as exhibits, films and literature upon request.

* * *

Dr. Wilder Penfield of Montreal, Canada, Director of the Neurological Institute and Professor of Neurosurgery at McGill University, will give the fifth E. Starr Judd Lecture at the University of Minnesota in the Medical Science Amphitheater on Wednesday, February 2, at 8:15 p. m. The subject of Dr. Penfield's lecture is "Cerebral Circulation in Epilepsy." The late E. Starr Judd, an alumnus of the Medical School of the University of Minnesota, established this annual lectureship in surgery a few years before his death.

* * *

Excerpt from a recent letter from the Secretary of the United States Treasury to the Attorney-General:

(Appointment of Consulting Specialists in Psychiatry by the U. S. Public Health Service)

"The Department has, upon the recommendation of the Surgeon-General, appointed as Consulting Specialists in Psychiatry the following physicians: Dr. Joseph C. Michael, 1945 Medical Arts Bldg., Minneapolis, Minn., Dr. Ernest Martin Hammes, 1125 Lowry Medical Arts Bldg., Saint Paul, Minn.; Dr. William Howard Hengstler, 1068 Lowry Medical Arts Bldg., Saint Paul, Minn.; Dr. Gordon R. Kamman, 350 St. Peter Street, Saint Paul, Minn., and Dr. Frank White Whitmore, 1017 Lowry Medical Arts Bldg., Saint Paul, Minn. . . . These specialists will, upon the request and only upon the request of the court, examine any person held pursuant to a law of the United States, and will submit consultive advice and report to the court showing the mental status of such person or the need of further mental examination and observation.

"The Department desires to take this opportunity of stressing the fact that the nature of the service to be furnished under the above arrangement is consultive and advisory to the court, and also wishes to invite attention to the importance of a realization on the part of all judicial, prosecution, and enforcement officers, as well as defense counsel, that this service is not for the purpose of determining the guilt or innocence of an accused; it is intended only to assist the court to determine the mental state of a defendant as one element in the problem of the disposition to be made of a case."

1938 AMERICAN MEDICAL ASSOCIATION MEETING—SAN FRANCISCO

When San Francisco was selected as the host city for the 1938 Annual Session of The American Medical Association, the profession of this Golden Gate Metropolis promptly initiated plans for the comfort, pleasure and entertainment of all who come to that national meeting. A local executive committee on arrangements, composed of five members with Doctor Howard Morrow as General Chairman and Doctor Frederick C. Warnshuis as General Secretary, and eighteen sub-committees have been busy since July in developing plans and local arrangement details. Their objective is the biggest, best, and most memorable annual session in the history of the American Medical Association.

Atlantic City, Kansas City, Cleveland, Detroit, with their known facilities and attractions, have been host cities in recent years, and have justified their selection as meeting places. However, and without disparagement, none of them possess the background, the setting, the resources, the history and romance, or the facilities that are found in San Francisco and in the great state of California—the Golden Bear Empire of the Pacific Coast. To reveal these, to extend California's and San Francisco's noted hospitality, and to cause those who plan to attend the 1938 session to experience ten days of profit and pleasure midst the environs of the annual meeting city, is the goal toward which the local profession is pointing.

The Local Committee on Arrangements cordially invites the profession of the country to be San Francisco's guests this coming June. Decide now to attend the 1938 American Medical Association Meeting and plan accordingly. During the coming months an insight to some of the feature functions will be disclosed, but the final details and program of events will not be revealed until you arrive. You will long regret it if you fail to attend the coming national meeting. Talk it over tonight with the good wife and your professional associates, and join the party of your state members that is coming to San Francisco—June 12th to 17th, 1938.

THE AMERICAN BOARD OF INTERNAL MEDICINE

The American Board of Internal Medicine will hold its next written examination on Monday, February 14, 1938, in various centers of the United States and Canada.

The examination will consist of two sessions of three hours each with the morning session held at 9:00 o'clock a. m. and the afternoon session held at 2:00 o'clock p. m.

The candidates who are successful in this written examination will be eligible to take the practical examination which will be held in San Francisco the Friday and Saturday prior to the opening of the Annual Session of the American Medical Association in June, 1938.

The final date for filing applications for this written examination is January 15, 1938, and all applications should be in the office of the chairman before that date.

For further particulars and application blanks please address Dr. Walter L. Bierring, M.D., Chairman, American Board of Internal Medicine, Suite 1210, 406 Sixth Avenue, Des Moines, Iowa.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The next examination (written and review of case histories) for Group B candidates who have filed applications will be held in various cities of the United States and Canada, on Saturday, February 5, 1938.

The general oral, clinical and pathological examinations for all candidates (Groups A and B) will be conducted by the entire Board, meeting in San Francisco, California, on June 13 and 14, 1938, immediately prior to the meeting of the American Medical Association.

Applications for admission to the June, 1938, Group A examinations must be on an official application form and filed in the Secretary's Office before April 1, 1938.

For further information and application blanks address Dr. Paul Titus, Secretary, 1015 Highland Building, Pittsburgh (6), Pa.

STATE MEETING

Dr. Howard W. Haggard, of Yale, famous lecturer and writer, is one of several distinguished medical guests who will address the Minnesota State Medical Association at its 85th Annual Meeting in Duluth, June 29, 30 and July 1, at the Hotel Duluth.

Dr. Haggard will talk to the doctors at the banquet to be held on the evening of June 30. He will also address an evening health meeting to which the public is to be invited.

Dates for the meeting were set in advance of the Fourth of July holiday and at the beginning of the vacation season in the North, so that physicians and their families could combine a vacation with attendance at the meeting.

Medical men from all of the Northwest states are expected to take advantage of the opportunity.

The scientific program, now practically completed, calls for sessions on fractures, on obstetrics and pediatrics, eye, ear, nose and throat, and on use of newer drugs, also a session of clinics in the Duluth hospitals.

Exhibits and demonstrations will be a feature of the meeting.

INSTITUTE IN OPHTHALMOLOGY AND OTOLARYNGOLOGY

January 17 to 22, 1938

The next seminar for medical graduates at the Center for Continuation Study of the University of Minnesota will be on Ophthalmology and Otolaryngology, January 17 to 22, 1938. The program will occupy the full time of the physicians from Monday morning to Saturday evening. There will be no evening lectures, but a feature of the institute will be a joint meeting on Friday evening, January 21, with the Minnesota Academy of Ophthalmology and Otolaryngology.

The seminar will consist of clinics, round table discussions, and lectures illustrated by lantern slides, charts or patients. The teaching staff has been selected from the Departments of Ophthalmology and Otolaryngology of the University Medical School, Minneapolis, the Mayo Clinic, Rochester, and the General Extension Division. The meetings will be held in the Center for Continuation Study, and in the University of Minnesota Hospitals and affiliated institutions in Minneapolis and St. Paul.

It is to be noted that much of the course will be devoted to intimate clinical instruction or conferences. Those who plan to register should make their reservations as soon as possible so that proper arrangements can be made for the clinics.

Program

Monday, January 17, 1938

Morning

9:00-10:00 The Early Diagnosis and Treatment of Hearing Deficiencies, Dr. Newhart.
10:00-11:30 Operative Clinic, University Hospitals, Drs. Boies and Bryant.
11:30-12:30 Pathology of Ear, Nose and Throat Diseases, Dr. Connor.

Afternoon

2:00- 3:00 Dispensary Clinic, University Hospitals, Drs. Boies and Fjelstad.
3:00- 4:00 Malignant Tumors of the Larynx, Dr. New.
4:30- 6:00 Round Table, Surgery of Acute Mastoiditis, Dr. Boies.

Tuesday, January 18, 1938

Morning

9:00-10:00 Pitfalls in Diagnosis and Treatment of Diseases of the Eye, Dr. J. S. Macnie
10:00-11:00 External Diseases of the Eye, Dr. Pfunder.
11:00-12:00 Pathology of Eye Diseases, Dr. Camp.

Afternoon

2:00- 3:00 Dispensary Clinic, University Hospitals, Dr. Hymes and Associates.
3:00- 4:30 Eye Operative Clinic, University Hospitals, Dr. J. S. Macnie.
5:00- 6:00 Round Table, Ophthalmological Problems, Dr. Benedict.

Wednesday, January 19, 1938

Morning

9:00-12:00 Dry and Operative Clinics, Ancker Hospital, St. Paul, Drs. Leavenworth, Hochfilzer and Associates.

Afternoon

2:00- 3:00 Endoscopic Procedures with Special Reference to Hoarseness and Dysphagia, Dr. Phelps.
3:00- 4:00 Management of Acute and Chronic Sinusitis, Dr. Bryant.
4:30- 6:00 Round Table, Nasal Obstruction, Dr. Hochfilzer.

Thursday, January 20, 1938

Morning

9:00-10:00 Surgery of Optical Muscles, Dr. Grant.
10:00-11:00 Fundus Findings in Blood Dyscrasias, Dr. Stanford.
11:00-12:00 Ocular Neurology, Dr. Ed. Burch.

Afternoon

2:00- 3:00 Dispensary Clinic, University Hospitals, Dr. Hanson and Associates.
3:00- 4:00 Eye Operative Clinic, University Hospitals, Dr. J. P. Macnie.
5:00- 6:00 Round Table and Pictures, Intraocular Operation, Dr. Spratt.

Friday, January 21, 1938

Morning

9:00-10:00 Demonstrations of Neurology of Eye, Ear, Nose and Throat, Room 214, Anatomy Building, University, Drs. Rasmussen and Newhart.
10:00-11:30 Operative Clinic, University Hospitals, Drs. Boies and Williams.
11:30-12:30 The Management of Chronic Otitis Media, Dr. Williams.

Afternoon

2:00- 3:00 Dispensary Clinic, University Hospitals, Drs. Newhart, Delavan and Bryant.
3:00- 4:00 Physiology of the Nose as the Basis for Treatment, Dr. Hilding.
4:30- 6:30 Round Tables (Visiting Clinicians). Section I, Ear, Nose and Throat; Section II, Eye.
6:30 Dinner meeting with Minnesota Academy of Ophthalmology and Otolaryngology. Speakers: Dr. J. P. Macnie, "Detached Retina"; and Dr. Thomas C. Galloway, in the Ear, Nose and Throat field, subject to be announced later by the Academy.

Saturday, January 22, 1938

Morning

9:00-10:00 Photography of Fundus, Dr. Fellows.
10:00-11:00 Ophthalmoscopy, Dr. Rucker.
11:00-12:00 Some Clinical Problems in Refraction, Dr. Prangen.

Afternoon

1:00- 3:30 Refraction Clinic, University Hospitals, Drs. Houkom, Hymes and Sandt (with a lecture by the latter on Contact Glasses).

3:30- 4:30 Allergy of Eye, Ear, Nose and Throat, Dr. Hilding.

5:00- 6:00 Round Table, Ocular Muscles and Orthoptics, Dr. Walter Fink.

Faculty

Harold S. Diehl, Professor of Preventive Medicine and Public Health, Dean of Medical Sciences, Medical School, Minneapolis.
James M. Hayes, Assistant Professor of Surgery, President, Minnesota State Medical Association, Minneapolis.
William A. O'Brien, Associate Professor of Pathology, Preventive Medicine and Public Health, Medical School. Medical Representative, Center for Continuation Study, St. Paul.
William L. Benedict, Professor of Ophthalmology, Mayo Clinic, Rochester.
Lawrence R. Boies, Assistant Professor of Otolaryngology, Medical School, Minneapolis.
Edward Burch, Special Lecturer, General Extension Division, St. Paul.
Frank L. Bryant, Instructor of Otolaryngology, Medical School, Minneapolis.
Walter E. Camp, Assistant Professor of Ophthalmology, Medical School, Minneapolis.
Charles E. Connor, Assistant Professor of Otolaryngology, Medical School, St. Paul.
Philip A. Delavan, Instructor of Otolaryngology, Medical School, St. Paul.
Manley F. Fellows, Special Lecturer, General Extension Division, Duluth.
Walter H. Fink, Instructor of Ophthalmology, Medical School, Minneapolis.
C. Alford Fjelstad, Assistant Professor of Otolaryngology, Medical School, Minneapolis.
Thomas C. Galloway, Evanston, Illinois, Guest Lecturer.
Hendrie W. Grant, Clinical Assistant Professor of Ophthalmology, Medical School, St. Paul.
Erling W. Hansen, Assistant Professor of Ophthalmology, Medical School, Minneapolis.
Anderson Hilding, Special Lecturer, General Extension Division, Duluth.
John J. Hochfilzer, Special Lecturer, General Extension Division, St. Paul.
Bjarne Houkom, Clinical Instructor of Ophthalmology, Medical School, Minneapolis.
Charles Hymes, Clinical Assistant Professor of Ophthalmology, Medical School, Minneapolis.
R. O. Leavenworth, Special Lecturer, General Extension Division, St. Paul.
John S. Macnie, Associate Professor of Ophthalmology, Medical School, Minneapolis.
John P. Macnie, Eye Institute, Medical Center, New York City, Guest Lecturer.
Gordon B. New, Professor of Laryngology, Oral and Plastic Surgery, Mayo Clinic, Rochester.
Horace Newhart, Professor of Otolaryngology, Rhinology, and Laryngology, and Director Division, Medical School, Minneapolis.
Malcolm C. Pfunder, Clinical Assistant of Ophthalmology, Medical School, Minneapolis.
Kenneth A. Phelps, Assistant Professor of Otolaryngology, Medical School, Minneapolis.
Avery D. Prangen, Associate Professor of Ophthalmology, Mayo Clinic, Rochester.
Andrew T. Rasmussen, Professor of Anatomy, Medical School, Minneapolis.
Charles W. Rucker, Assistant Professor of Ophthalmology, Mayo Clinic, Rochester.
Karl E. Sandt, Physician, Students' Health Service, Minneapolis.
Charles Spratt, Special Lecturer, General Extension Division, Minneapolis.
Charles E. Stanford, Physician, Students' Health Service, Minneapolis.
Henry L. Williams, Assistant Professor of Otolaryngology, Mayo Clinic, Rochester.

NOTE: Write to the Director for information, Center for Continuation Study, Minneapolis, about this and future institutes.

Medical Diagnosis and Treatment, February 7-12, 1938.

Traumatic Surgery, March 7-12, 1938.

EAST CENTRAL MINNESOTA SOCIETY

The East Central Minnesota Medical Society held its annual meeting on November 29, 1937, at the Colony for Epileptics, in Cambridge, Minnesota.

Dr. Donald Brink of Isle, Minnesota, and Dr. George Haliday of Rush City, Minnesota, were elected to membership in the society. Dr. G. L. Richey, formerly of Rochester, Minnesota, was accepted as a transfer into this society.

The following officers were elected for the coming year: Dr. George H. Schlesselman of Anoka, president; Dr. A. B. Roehlke of Elk River, vice president; Dr. Claire M. Ness of Cambridge, secretary-treasurer; Dr. H. C. Cooney of Princeton, delegate; and Dr. W. T. Nordman of Mora, alternate delegate.

Dinner was served and in the evening a scientific program was presented by guest speakers. Dr. A. W. Adson of the Mayo Clinic in Rochester, president of the Minnesota State Medical Society, spoke on the surgical treatment of hypertension. Dr. A. P. Dunnigan of the State Board of Health demonstrated the Neufield typing in pneumonia and explained the pneumonia service which is now available to physicians in this state.

KANDIYOHI-SWIFT-MEEKER COUNTY SOCIETY

The December meeting of the Kandiyohi-Swift-Meeker County Medical Society was held at the Lakeland Hotel, Willmar, on Wednesday, December 8.

Dr. J. K. Anderson of Minneapolis was the guest speaker, the subject being "The Office Treatment and Diagnosis of the Common Rectal Diseases."

The following officers were elected for 1938: Lennox Danielson, M.D., president-elect; Magnus Pederson, M.D., vice president; C. L. Scofield, M.D., secretary-treasurer; Karl Danielson, M.D., advisory committee, three years; C. L. Scofield, M.D., delegate, and J. C. Jacobs, M.D., alternate.

MOWER COUNTY SOCIETY

These officers of the Mower County Medical Society were all reëlected for 1938 at the annual meeting of the society on November 23: President, Dr. Paul C. Leck, Austin; vice president, Dr. R. S. Hegge, Austin; secretary, Dr. Paul A. Robertson, Austin; treasurer, Dr. A. E. Henslin, LeRoy.

PARK REGION MEDICAL SOCIETY

The annual meeting of the Park Region Medical Society was held on Wednesday evening, December 15, at the River Inn at Fergus Falls. About sixty physicians were present.

The principal speakers of the evening were Dr. J. A. Bargen and Dr. H. M. Weber, both of Rochester, Minnesota.

The following officers were elected for 1938: L. C. Combacker, M.D., president; Norman H. Baker, M.D., president-elect; C. J. Lund, M.D., vice president; T. S. Paulson, M.D., treasurer, and C. A. Boline, M.D., secretary.

RAMSEY COUNTY SOCIETY

Dr. R. B. J. Schoch, city health officer of Saint Paul, was elected president-elect of the Ramsey County Medical Society at the last meeting of the Society. Dr. James N. Dunn will take office as president on January 1. Other officers elected for 1938 are Dr. W. D. Brodie, vice president, and Dr. J. Allen Wilson, secretary-treasurer.

RED RIVER VALLEY MEDICAL SOCIETY

The annual meeting of the Red River Valley Medical Society was held at the Hotel Crookston in Crookston, on Tuesday, December 14.

Addresses on different phases of medical economics were given by Dr. L. J. McLeod of Grand Rapids, Dr. B. J. Branton of Willmar, and Dr. W. L. Burnap of Fergus Falls.

The following officers were elected for 1938: Baldwin Borreson, M.D., president; Eskil Erickson, M.D., vice president; C. L. Oppegaard, M.D., secretary-treasurer; J. A. Roy, M.D., and G. A. Morley, M.D., censors; J. F. Norman, M.D., and H. M. Blegen, M.D., delegates to the state convention.

ST. LOUIS COUNTY SOCIETY

Officers for 1938 for the St. Louis County Medical Society are: President, Dr. Malcolm G. Gillespie, Duluth; vice president, Dr. F. W. S. Raiter, Cloquet; president-elect, Dr. Gage Clement, Duluth; secretary-treasurer, Dr. Gordon C. MacRae, Duluth (reëlected); delegate, Dr. Harry Klein, Duluth; alternate, Dr. C. Jacobson, Chisholm.

SOUTHWESTERN MINNESOTA SOCIETY

At the annual meeting of the Southwestern Minnesota Medical Society, the following officers were elected: President, Dr. C. L. Sherman, Luverne; vice president, Dr. J. D. Waller, Wilmont; delegates, Dr. C. L. Sherman, Luverne and Dr. S. A. Slater, Worthington (reëlected); alternates, Dr. J. D. Waller, Wilmont and Dr. W. A. Piper, Mountain Lake. Dr. H. DeBoer was reëlected secretary-treasurer.

WASHINGTON COUNTY SOCIETY

The following officers were elected at the annual meeting of the Washington County Medical Society: President, Dr. Robert P. Ewald, Newport; first vice president, Dr. F. M. McCarten, Stillwater; second vice president, Dr. James H. Haines, Stillwater; secretary-treasurer, Dr. E. Sydney Boleyn, Stillwater (reëlected); delegate, Dr. E. Sydney Boleyn, Stillwater (reëlected); alternate, Dr. W. R. Humphrey, Stillwater (reëlected).

WOMAN'S AUXILIARY

Mrs. J. F. Norman, Crookston, *President*
Mrs. A. A. Passer, Olivia, *Editor*

The Woman's Auxiliary again coöperated in the seventh Annual Christmas Seal High School Radio Contest which is sponsored by the Minnesota Public Health Association, and donated the awards. A total of one hundred talks were entered by the high schools of Minnesota and the judges, Dr. Kathleen Jordan of Granite Falls, Miss Melba Hurd of the University of Minnesota, and Mrs. Martin Nordland of Minneapolis, have announced the winners.

The ten best talks were broadcast over WCCO.

Mrs. F. A. Erb of Minneapolis, member of the Hennepin County Auxiliary, was in charge of the downtown Christmas Seal pay station at 612 Marquette Avenue which opened November 28 for the convenience of Christmas shoppers. A large group of volunteers, representing many organizations, assisted Mrs. Erb at the station throughout the holiday season. Proceeds from the sale of Christmas Seals go to support the tuberculosis prevention work.

Hennepin County Auxiliary

The Annual Glen Lake Sale was held at Dayton's November 18, 19 and 20, in charge of Mrs. E. S. Mariette and the Philanthropic Committee of the Hennepin County Auxiliary. The articles for sale are made by the Glen Lake Sanatorium patients and include knitted garments, toys, embroidered linens, leather goods and many novelties. Proceeds of the sale go to the patients.

The Annual Christmas party of the Hennepin County Auxiliary was held in the Hennepin County Medical Library, Friday, December 3, with the Social committee in charge of arrangements. Miss Mae Martin presented three puppet plays. Community singing of carols was led by Mrs. Herbert Jones and gifts were distributed by Mrs. H. B. Hannah, chairman of the Social Committee.

Renville County Auxiliary

Mrs. R. C. Adams, Bird Island, president of the auxiliary, entertained the members at her home Tuesday afternoon, December 7. Following the business session the auxiliary members joined their husbands at a banquet served in the Methodist Church dining hall. Music was furnished by the Bird Island High School Quartet. Dr. W. A. Brand, Redwood Falls, showed moving pictures including the national medical convention in Atlantic City and of the Renville County Society's annual picnic at Green Lake.

Mrs. H. B. Copeland of Cresco, Penn., an instructor in a school for the deaf in New York City, gave a talk on the "Care of Deafness." Very hard of hearing, she is a graduate of the Nitchie lip reading school of New York and did graduate work at Columbia.

Meeting of October 13, 1937

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, October 13, 1937. Dinner was served at 7 o'clock and the meeting was called to order at 8 o'clock by the president, Dr. E. M. Jones.

There were forty-three members present.

Minutes of the May meeting were read and approved.

The scientific program followed.

BROMIDES, THEIR USE AND ABUSE

GORDON R. KAMMAN, M.D., F.A.C.P.
Saint Paul

Dr. Gordon Kamman read his Inaugural Thesis on the above subject.

Abstract

Due to the increase in functional nervous diseases, more sedatives are being prescribed than formerly. One of trese sedatives is bromide, and, in susceptible individuals, bromides may produce mental symptoms even when given in therapeutic doses. The effects of bromide are confined largely to the central nervous system. The drug tends to replace chloride in the blood stream; so, with the administration of bromide, an adequate intake of chloride is necessary to prevent bromide intoxication.

The toxic effect of bromide may be described as simple bromide intoxication or depression, and bromide delirium or psychosis. Blood serum bromide in excess of 150 mgm. per 100 c.c. is said to be in the "toxic zone." The duration of symptoms of brominism following discontinuance of the drug is two to six weeks, and is roughly proportional to the length of time the symptoms existed prior to withdrawal.

The treatment of bromide intoxication consists of discontinuing the drug and all other sedatives; the administration of NaCl orally and parenterally; hydrotherapy, and, in urgent cases, quick acting and rapidly eliminated sedatives. Spinal drainage sometimes helps, and gastric aspiration has been recommended to help eliminate the bromide as the drug is reëxcreted into the stomach.

Three probable cases and three proven cases are reported.

Discussion

DR. GEORGE N. RUHBERG, St. Paul: Dr. Kamman is to be congratulated in presenting this timely and practical paper. My experience with bromide poisoning has occurred mainly among two types of cases. The first, in elderly people in whom arteriosclerosis and poor elimination tend to hasten mild symptoms of bromide poisoning. The second, are usually cases of severe functional neurosis, often seen in hospital consultation work, in whom marked symptoms of insomnia, agitation and excitement are present to a more or less marked degree. The usual amounts of sedatives have not sufficed and, therefore, these have been repeatedly increased and continued until a toxic factor has been definitely established. Many of these cases are noisy and difficult to be taken care of properly in a general hospital. This condition also is seen occasionally in people who do not return to a doctor's office after obtaining an original prescription, but continue on their own, refilling the original until toxic symptoms have developed. In spite of all this, bromides have been, and I believe are, one of our most valuable sedatives when properly used.

DR. W. H. HENGSTLER, St. Paul: I also want to express my appreciation of Dr. Kamman's paper on this very pertinent subject, and the able presentation which he gave. I believe those of us who are interested in psychiatry are beginning to draw away from so much drug medication. We are prescribing less bromide and less of the heavy sedatives than we did ten years ago; and we are turning more to hydrotherapy than we used to. The fact that all people do not react the same way to the same drug must be taken into consideration. The use of bromides in the hospital, where the patient is under close observation, is justifiable, but the office patient should be told that the bromide prescription cannot be refilled without doctor's orders. A great many people know what bromides are and they buy them across the counter at drug stores; and the same is true of a great many other sedatives. We are not prescribing veronal as we used to and, in fact, we are eliminating, as far as possible, the use of all heavy and depressing sedatives.

DR. S. E. SWEITZER, Minneapolis: I wish to congratulate Dr. Kamman on a very fine paper. In a dermatological clinic, it has been my custom to withdraw bromides; most patients are better off without it than with it. As far as retention of bromides in the body is concerned, Wile stated that bromides would stay in the body as long as nine months. Bromide lesions on the skin stay there for a long while and Wile felt that the reason they did last so long was due to the fact that bromide stays in the body for so long; he recommended the use of chloride to eliminate the bromine. A patient who is getting bromine should be watched very carefully for some patients are more susceptible to it than others. Some patients will take only one dose of iodin and get an eruption, and often a small dose of bromine will do the same.

DR. H. Z. GIFFIN, Rochester: Does Dr. Kamman think we should prescribe salt as a routine when we prescribe bromide, and will the administration of salt prevent bromide eruption?

DR. KAMMAN (in closing): I wish to thank the gentlemen for their discussion. In answer to Dr. Giffin, it has been calculated that one should give four times as much chloride as bromide. If bromide and chloride intake are equal, intoxication is likely to occur in about three weeks. I do not know what effect an increased chloride intake would have in the prevention of skin lesions; probably the dermatologists could tell us more about that. Sir William Osler once said that a physician's skill stands in inverse proportion to the amount of opium and opium derivatives he prescribes. I think that remark might be extended to include bromide and embrace the therapeutic efforts of neuropsychiatrists.

THE ADMINISTRATION OF YELLOW BONE MARROW IN AGRANULOCYTIC ANGINA

HERBERT Z. GIFFIN, M.D., and
CHARLES H. WATKINS, M.D.
The Mayo Clinic, Rochester

Dr. H. Z. Giffin read a paper on the above subject.

Abstract

In studies made in 1928 and 1929, on the effects of the administration of bone marrow for secondary anemia, a moderate increase in the number of neutrophils and monocytes was observed in blood smears. This observation led to the administration of bone marrow in cases of granulocytopenia. The first patient with agranulocytic angina in the series was treated with bone marrow in July, 1930. Since then, twenty-four patients with agranulocytic angina have been treated with bone marrow and without other treatment than nursing care. The series includes all cases of agranulocytic angina in which an attempt was made to administer bone marrow, including those in which it was impossible, for one reason or another, to administer a sufficient amount, those in which the patients were in such serious condition that recovery could hardly be expected, and those in which patients had recovered from a former attack but could not obtain bone marrow during the fatal attack at home.

In the response during recovery, the first cells to increase in number are the monocytes, these cells not infrequently increasing to 10 or 20 per cent in the differential count. An increase up to 40 per cent has been observed. Following this, there is an increase in the number of neutrophils as the percentage of monocytes decreases. Myelocytes and even promyelocytes are seen many times during the early period of recovery. The percentage of neutrophils increases steadily to a level of 25 or 30, after which time there is a slower rise. By the end of the second week the percentage of neutrophils is approximately normal and the total leukocyte count is normal or above normal. The blood picture, however, is not regarded as entirely satisfactory until eosinophils and basophils appear.

There is apriori no reason to think that bone marrow should contain a material which produces this effect, as it consists mostly of fat, but, since even the yellow marrow contains many reticular cells and may potentially under stress be replaced by red marrow, there may be some substance retained which, when taken internally, has the power of stimulating the production or maturation of leukocytes.

Early in our experience, small doses of bone marrow were administered, with some benefit; the response was not nearly as rapid, however, as that which has been obtained with larger doses. At present we feel that the initial dose should be from 200 to 300 grains (13 to 20 gm.) daily; one patient was given as much as 800 grains (52 gm.) daily. This necessitates the swallowing of from 75 to 100 pearls of bone-marrow extract* in twenty-four hours. This is usually not difficult except in cases in which severe ulceration or edema of the larynx is present. After recovery we have reduced the dose of bone marrow, keeping the patients on a maintenance dose of 50 to 100 grains (3.3 to 6.5 gm.) daily, for a period of three or four months longer. By this means, subsequent relapses apparently in most cases have been avoided.

As has been said, twenty-four patients with agranulocytic angina have been treated since 1930. Of this number, three were unable to obtain bone marrow during the fatal attack after having recovered from former attacks while taking bone marrow. Five were unable to take an adequate dose because of extreme illness: ulceration, edema of the larynx, nausea and vomiting. Two patients died even though an adequate dose had been given, one apparently of perforation of the bowel with peritonitis and the other of gas gangrene. The remaining fourteen patients are now living, having recovered from as many as one to four attacks. The total number of attacks in the series was twenty-nine. The number of attacks in which an inadequate dose or no bone marrow at all was given (the patients formerly having received bone marrow) was eight. The number of attacks in which adequate amounts of bone marrow were given and yet in which death resulted were two. Patients recovered from the remaining nineteen attacks. The average percentage of neutrophils on admission was 8, the average percentage ten days later, 58. The average leukocyte count on admission was 1200 per cu. mm. of blood; the average count, ten days later, 7800.

While the results of treatment of agranulocytic angina by any method are especially liable to lead to fallacious conclusions because of the frequency of spontaneous recoveries, our experience with the administration of bone marrow has, nevertheless, been sufficiently satisfactory to warrant a continuation of its administration to the exclusion, at least temporarily, of other methods of treatment such as liver extract, transfusion, and "pentnucleotide." When multiple methods of treatment are used, one cannot arrive at any sort of conclusion concerning the effectiveness of bone marrow or any other form of treatment. An accurate diagnosis is essential, and leukopenic leukemia, particularly of the monocytic type, and aplastic anemia, must especially be differentiated.

Discussion

DR. W. F. BRAASCH, Rochester: In these cases of agranulocytosis, following the use of sulfanilamide, would you use other measures than stopping the administration of the drug? Would you use bone marrow? Would it have an immediate effect?

DR. GIFFIN: I do not know whether it is advisable to use any method of treatment in cases in which the condition is apparently due to sulfanilamide. It may be that stopping administration of the drug is sufficient.

DR. C. B. WRIGHT, Minneapolis: This is a very interesting paper because of the number of cases re-

*Yellow bone-marrow extract, 3⅓ grain capsules, Frederick Stearns and Company, Detroit, Michigan.

ported and the length of time they have been followed. In fact, it is the largest series that I can recall seeing reported in the experience of any one man. We are recognizing more of these cases. It is true the final illness is usually very acute and tragic. We are learning more and more that these patients may have had previous attacks from which they recovered. I recently saw such a case. Her death was sudden, with high fever, normal red blood count, and a rapid disappearance of granulocytes from the blood. Transfusion did not help. Injections of blood did not help. On reviewing a previous hospitalization a year before when the patient was in for an abscess, the blood count showed that she had a marked drop in both the number of white cells and more marked still in the number of granulocytes. She promptly recovered from this attack but the last count recorded did not show a complete return to normal. In the four or five cases of this disease I have seen in practice, various procedures were tried such as pentnucleotide and trans fusions. As far as could be determined, these measures had no effect on the disease. Dr. Giffin's high percentage of recoveries with the use of bone-marrow extract certainly is encouraging. As Dr. Giffin says, the cause of this condition is still undetermined. There must be something more fundamental than a mere drug reaction. Whether or not a drug reaction is an allergic reaction is not entirely agreed upon by dermatologists. Recent reports of sulfanilamide would indicate that the condition disappears rapidly with the removal of the drug. Undoubtedly, many cases recover spon taneously from attacks. With his record of recoveries from the use of yellow bone marrow, Dr. Giffin certainly should continue its use and it is hoped that some more concentrated extract may be obtained. I would like to ask Dr. Giffin if there was any way of determining in any given attack whether the outcome would or would not be fatal?

Dr. Moses Barron, Minneapolis: Dr. Giffin was the first one to get me interested in yellow bone marrow for the treatment of agranulocytosis. It is very difficult to evaluate any kind of therapeutic measure in the treatment of this disease. The first case presented by Dr. Giffin was that of a pregnant woman who received bone marrow after the sixth day and recovered. The serious feature of this disease is that the patients may die from the second to the fifth or sixth day of this disease and if they live longer than that, many recover without any special treatment.

As Dr. Giffin emphasized, most of us do not wish to determine the efficiency of any special therapeutic agent and, for my own part, I give pentnucleotide, yellow bone marrow and liver extract all at the same time, as soon as I arrive at the diagnosis. The pathogenesis of the disease is still not understood. As Dr. Giffin pointed out, there should be no anemia along with the leukopenia for the correct diagnosis. If there is also a marked anemia present, then we must rule out other conditions such as acute leukemias and aplastic anemias.

One difficulty in the use of bone marrow is that the patients have such sore throats and find it difficult to swallow the large bulk of bone marrow necessary.

Cases in which the leukocyte count is under 300 or 400 are very serious and a large percentage die no matter what the treatment. Transfusions and x-ray treatment for stimulation of the bone marrow are practically of no value. So far, we have nothing better than the measures mentioned.

Amidopyrine may have some etiological relationship in some cases and it is not the size of the dose given but, apparently, the patient's sensitiveness to the drug which results in the leukopenia.

Prontylin has been reported to produce agranulocytosis. The nucleus in the chemical structure of prontylin is similar to that of amidopyrine. Personally, I use amidopyrine a great deal and have thus far not seen a single case of agranulocytosis develop from it. At the meeting of the Central Society for Clinical Research in Chicago, three years ago, the relationship of amidopyrine to agranulocytosis was emphasized and Dr. Watkins of Rochester cited cases where the blood condition was cleared up after withholding the drug and reappeared upon administering it again. Bone marrow, along with other measures, should be used in the treatment of agranulocytosis.

Dr. Alfred Hoff, St. Paul: There are many papers about the effects of drugs, such as the barbiturates and amidopyrine, upon the bone marrow. I have had the misfortune in my own practice to have had four cases of agranulocytosis; three cases followed the use of allonal. I would like to emphasize what both Dr. Barron and Dr. Giffin said about the diagnosis. We see so much of leukopenia and we immediately begin to think what it means. Unless we have a very definite conception of what leukopenia signifies, we are in difficulty. I recall one patient at Ancker Hospital who showed various blood counts over a period of years. First she had a thyroidectomy. Her next operation was a gallbladder, and later she had backache, which was supposed to be due to some ureteral kink, and the kidney was operated upon. The patient finally came in with marked sore throat and a marked anemia and profound leukopenia. She had been given salvarsan for a Vincent's infection. Just before she died, a few immature cells were found. Autopsy revealed leukemic infiltrations in the liver and kidneys. The picture of anemia is so important in cases of agranulocytosis. We must recognize that, if the patient has anemia, we probably are not dealing with agranulocytosis.

About the treatment, I have one patient who has been well for two years. She just returned from a trip to Europe and I saw her the other day and she is perfectly well. I tried pentnucleotide. I had her husband go down to the butcher shop and get all the bone marrow he could; this was given orally, also liver extract intramuscularly. She had taken allonal for three years. She has not taken any allonal for the past two years and has remained well. I think the fundamental thing of the whole problem is, that whatever the causative action may be, there is a sensitivity in the individual. When that sensitization is recognized and the offending agent that produced the leukopenia is removed, then I think the patient will get well in the chronic recurring type of case. Bone marrow is probably an excellent thing.

Dr. Giffin (in closing): I wish to thank the gentlemen for their discussions. In answer to Dr. Wright, I have found it almost impossible to decide beforehand whether or not a patient is likely to recover. Patients who have had edema of the larynx or incipient pneumonia at the time of admission have not survived. In the series of cases reported, patients with edema of the larynx have not been able to swallow bone-marrow capsules. The two patients who died while receiving an adequate amount of bone marrow had severe complications; one had gas gangrene and the other an abdominal abscess.

The meeting adjourned.

A. G. Schulze, M.D.,
Secretary.

Meeting of November 10, 1937

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, November 10, 1937.

Dinner was served at 7 o'clock and the meeting called to order at 8:15 by the president, Dr. E. M. Jones.

There were fifty-two members present.

Minutes of the October meeting were read and approved.

The Secretary called attention of members presenting papers and theses to the fact that abstracts should be handed in at the time, for inclusion in the published Proceedings of the Academy.

The scientific program consisted of two papers.

SYMPTOMATOLOGY OF THE VARIOUS LEUKEMIA STATES

T. A. Peppard, M.D.
Minneapolis

Dr. Peppard read a paper on the above subject and illustrated it with slides and charts of cases.

Abstract

Charts showing symptoms complained of and the physical signs observed in a small group of cases of leukemia were presented.

Attention was called to the great variability of the manifestations of this disease. Complete detailed records presented in four cases illustrating these variations.

Discussion

Dr. H. L. Ulrich, Minneapolis: There is an immense amount of material in this study. Dr. Peppard deserves the applause and commendation of all of us for attempting such an analysis. It is difficult to discuss the rarer forms of leukemia because of our limited experience and its protean clinical manifestations. The leukemias are a paradise for the hematologist, although he gets lost in his paradise quite often. Because of the extreme difficulty in differentiating these various leukemias, I think Dr. Peppard is to be congratulated for making this clinical and hematological study.

Dr. S. E. Sweitzer, Minneapolis: This is the first time I have seen a group comprising a large number of internists who were speechless after a paper. I was extremely interested in Dr. Peppard's paper and particularly interested in the fact that he did not say much about leukemia as far as the dermatologist is concerned. I am sure he must have seen some dermatological symptoms. From our standpoint, practically all our cases present dermatological symptoms. Some have exfoliative dermatitis for a long while and finally turn into leukemia, and some have minor skin symptoms at first. Some have leukemia infiltration early and no blood symptoms. I recall a patient who had been to a clinic where they had made a diagnosis of lymphosarcoma. An operation was done on the neck and six or seven years later the patient was still alive. She came in with what looked like a syphilitic serpiginous eruption on the scalp. The Wassermann reaction was negative. Biopsy showed leukemia. The blood smear was turned over to Dr. Downey who made a tentative diagnosis of leukemia. That was last summer. She came in again recently with the same type of lesion on her back. She also complained of pain in the eyeball. Dr. Peppard mentioned this, but that was the first time that I had encountered this symptom. I gave her some x-ray over that area and she was relieved. That may have been imagination but she did get relief.

I want to emphasize the point that these patients may have lesions that would lead one to suspect leukemia and yet one can't find it when examining the blood.

Dr. Peppard (in closing): I thought I paid my respects to the dermatologists. In this group there were four who complained of skin conditions and ten who showed skin lesions on physical examination. As a rule, no biopsy is required for diagnosis for the blood examination usually suffices. However, in occasional cases, biopsy is invaluable. Whenever anyone interests himself in any one particular finding, his investigations will commonly show a higher incidence of such conditions than are found on routine examination.

THE IMPORTANCE OF IMMOBILIZATION AND POSTURE IN THE TREATMENT OF ACUTE INFECTIONS OF THE EXTREMITIES

Owen H. Wangensteen, M.D.
University Hospital

Dr. Wangensteen read a paper on the above subject, illustrated with lantern slides demonstrating methods of treatment and results.

Abstract

The rôle of the surgeon in the management of acute infections of the extremities has been reviewed. It is pointed out that his chief objective should be to assist the natural defense mechanism of the body in overcoming or localizing the infection. Other than that, his function is that of a pus evacuator—to incise an abscess when suppuration occurs.

The great virtue of rigid immobilization and elevation of the affected member in infection is described. It should be the aim of the surgeon to keep the infected extremity as quiet as physically possible; in addition, he should, through employment of elevation, strive to keep swelling at a minimum. The attainment of these objectives serves the natural defense mechanism of the body in a most helpful manner.

Discussion

Dr. A. E. Benjamin, Minneapolis: I was very glad, indeed, to have Dr. Wangensteen bring up this method of treating wounds, injuries, or infections. It has been my practice for a number of years, in cases of infection of the extremities, to elevate the part affected about as he has demonstrated by the cases shown here tonight. I have a few cases on hand now in which this is very well illustrated. Perhaps we may be able to obviate a great many operations by following this procedure. I would further include under this method of treatment, certain leg ulcers from varicose veins. If you put the patient in bed and elevate the leg, you will note how quickly the ulcers improve. I have practiced this method in other cases, such as pelvic inflammations without any definite abscess. Cases of endometritis and non-specific salpingitis will often get well if the foot of the bed is elevated. It has been my rule always to put an inflamed part above the normal circulatory level; the swelling then disappears around the inflamed area. If there is swelling there is not the drainage of the deeper parts that otherwise obtains; and the less swelling there is the better drainage there will be of the deeper tissues. In a case of ruptured appendix, besides instituting the

ordinary drainage treatment, the patient may be turned over on the abdomen. I recall one patient, a physician, who had an acute gangrenous appendix with abscess. I could not get the appendix out safely. I turned him over on his abdomen and the appendix sloughed out in three days. One should always put infection cases in a position which promotes drainage. They will recover faster that way.

I think the method of using casts, as Dr. Wangensteen has described, is a great help in treating certain cases.

Dr. L. C. Bacon, St. Paul: I listened to Dr. Wangensteen's talk with a great deal of pleasure. I am glad to hear him bring up old principles. They cannot be emphasized too much. It recalled my student days under de Nancrede. He taught that, in case of inflammation, rest and elevation of the part is the first thing to be done. It became monotonous to the students but it was repeated until it became a part of our daily lives.

Dr. J. Frank Corbett, Minneapolis: Dr. Wangensteen has given us a good deal of food for thought. I have lived long enough to see treatment of osteomyelitis progress. In the early days, wounds in the bones were opened, dressed every day, and then almost never got well. Then Orr advanced his method of treatment—complete immobilization in plaster casts, packing of the cleaned out area with vaseline and no dressing for a long time. That was a distinct advance. And now we come to another thought in regard to these cases. I recall the experience we had on the Mexican border in 1916. There were a good many gunshot wounds. That was a sterile, hot country where there was not much infection, but there were many compound fractures from gunshot wounds. Those healed very nicely without an antiseptic other than surface disinfection, but they were immobolized in plaster casts. Later on, in the World War, it was my lot to do a great number of reconstructvie operations. In wounds thought to be quiescent, infections did not occur following operation; I attributed it very largely to the fact that every one of these extremities was extensively encased in plaster, and there was absolute physiologic and complete rest to the body. However, infections vary. Every war has brought in its train a terrifically dangerous infection, and the infections of the last World War were severe in character and demanded radical treatment. We seem now to be one of the cycles of comparatively mild infection of wounds and the radical treatment of war days is no longer used.

Dr. Wangensteen's paper was very well presented.

Dr. H. P. Ritchie, St. Paul: I protest the use of Bier's hyperæmia treatment. Whatever the rationale, no cognizance is taken of the comfort of the patient. I was once subjected to this plan and testify that the method is barbarous.

I shall await, with great interest, the follow-up report on the treatment of burns by Dr. Wangensteen's plan for the fixation rest of the affected parts.

Dr. C. C. Chatterton, St. Paul: I heartily agree with Dr. Wangensteen in regard to rest and protection of parts affected with acute infection. Immobilization gives a patient comfort and prevents deformity. Until recently we were of the opinion that our treatment of osteomyelitis, so far as the end result is concerned, was perhaps superior to the treatment given years ago. In going over the records of the Gillette Hospital for Minnesota's crippled children, we find that the records of 30 or 40 years ago compare very favorably to the present records as to time in the hospital and time for the sinus to heal.

Dr. A. R. Colvin, St. Paul: The treatment of infections is perhaps the largest field of surgical endeavor and Dr. Wangensteen's paper has covered many aspects of it. His theme of "Rest in Pain" must be appreciated by all.

There is one thought concerning infections which should influence greatly our approach to the diagnosis, prognosis and treatment of infections; and that is the variability in virulence of the infecting agent and the very reliable reaction of individual tissues to infection; and, of course, our appraisal of the value of therapeutic measures—surgical or otherwise—must be influenced by an acknowledgement of these facts.

May I cite a few cases seemingly to confirm these inferences? A man of about 40 years (1908), with a suppurating tendon sheath opened on recognition, a few days later developed an abscess in the calf muscles of one leg and still a few days later developed an abscess in the other calf muscles. These were opened as soon as recognized; and very shortly there developed an acute non-suppurating infection of a shoulder and hip joint. Apparently there was no effusion, the joints were not opened, and recovery took place with saving of the tendon involved. Both joints recovered but had limited movement for some time. The closest observation was necessary to interpret the nature of the joint lesions—immediate opening saved the tendon. There, then, were different reactions of tissues at the same time in the same organism from the same infection.

The manifold nature of osteomyelitis is strikingly apparent. The infection may be fatal before there is time to do anything about it. At the other extreme is a small area of bone involvement, the size of a grain of wheat, which, as proven by radiographic study extending over a year, was entirely recovered from without any kind of treatment. There may be involvement of several bones, each bone presenting a different amount of invasion and a different grade of inflammatory reaction.

A girl of five years (1907), had five bones involved. The femur was involved in the lower third; at no time was there any operative surgery, the bone draining into the tissues of the thigh and thence through the skin. Radiographs taken at intervals showed the destruction and regeneration until at the end of a year the femur looked almost normal and remains so at the end of 30 years. The ulna showed a slow-going destruction and repair with the formation of a new shaft in the center of which were remnants of the old shaft as sequestra which had to be removed. In the humerus there was a small area about 1 cm. in length. Another child, with all the long bones of both extremities infected, presented with a very acute osteomyelitis of the femur which was opened at once. The child was very ill and, although relieved of pain, the entire femur became involved. While lying in bed, bone after bone became involved and one was conscious of this only when abscess after abscess was manifest and required opening in the various extremities. Except for the femur, first involved, the bones were not operated upon. There were no two lesions quite alike in extent of involvement. And it would seem that, as well as variability in virulence, there is a great variability also in the amount of bone involved. This, I believe to be explained by the extent of vascular territory involved by the embolic invasion; and, too, this is, as it were, at one assult.

A boy of six years was seen six weeks after the onset of trouble, in the meantime having been treated for arthritis of the knee. His physician was insistent that the femur be opened and, although pain and fever were receding, a small opening was made in the femur. There was no pus, the spongy bone was strikingly red, the small wound in the soft parts was partially closed

and finally closed completely. It was only after two months that an abscess in the soft parts was opened and in four months a sequestrum was removed.

A girl of fourteen with extreme pain and temperature of 101° to 104° lasting four months, presented herself with pain and swelling in the knee joint. The pain and elevated temperature suddenly subsided though no surgery had been done. Finally, a small abscess of the thigh opened spontaneously and ultimately a sequestrum was removed.

A boy fourteen, with multiple acute arthritis for 10 weeks and marked elevation of temperature, was reported by his physician who had at first very excusably diagnosed the case acute rheumatism. At the end of ten weeks all the joints except the hip and knee on one side were well. At that time the thigh was much swollen, there was very little pain, and the temperature was 101°. No operative measures were undertaken. He was observed for five years, during which time no abscess had as yet developed, and at this time a central sequestrum was removed.

Effusion in a joint contiguous to osteomyelitis rarely requires removal; usually it will be absorbed. The same variability as that in osteomyelitis is seen in joint infection and the treatment is just as variable. Numerous microörganisms may cause an arthritis varying from serous, fibrinous, purulent and phlegmonous. At times it is more important to know what the microörganism is doing rather than the name of it. And the treatment must be as varied as the process is variable. I am reminded of the visit of Ambroise Paré to the country to see a young man who was very ill. He said he found the young man in a most deplorable condition, lying in a filthy bed bathed in pus. He thought he could do nothing for the young man but, after taking a walk in the fields, he returned and ordered the patient bathed and supplied with clean sheets, and his thigh to be dressed with an infusion of fragrant herbs. He says that he had the pleasure of hearing that the young man recovered. I have often wondered if that case was one of neglected acute suppurative osteomyelitis. For pain, rest in bed is also valuable. Rest in a cast is of undoubted value and so is rest for the olfactories of the patient, surgeon and nurses—meaning sufficient change of dressing to accomplish this.

The treatment of chronic osteomyelitis is as variable as the result produced by the acute infection.

Just a few days ago I saw a patient on whom I operated thirty-two years ago for osteomyelitis of the lower end of the femur. He is now suffering from a very acute recrudescence of his former infection—after an interval of thirty-two years. After a few day of regrettable procrastination, a large amount of pus was evacuated from a cavity in the lower end of the bone. He will very likely never be completely cured of his trouble.

It is quite pertinent to ask when infection of bone is cured; and it is sad to say that a very large number are never cured. Microörganisms have become encapsulated in small areas of granulation tissue or in the lacunæ and canaliculi and Haversian canals of the cancellous bone which are rarely all reached by any kind of operative attack. Recurring fever and pain usually demand liberation of pus, all the more so because, in these recurring chronic cases, the pus is confined by thick-walled more or less sclerotic bone and the pain is very severe. One might say, in closing, that relief of tension by incision not only relieves pain but, in properly selected cases, leads to a subsidence of the inflammatory process.

Dr. Wangensteen (in closing): With the development of antisepsis and asepsis the scope of the surgeon's activity broadened considerably. His activity formerly had been concerned largely with the management of wounds. Despite his present greater field of interest, one of his major concerns is still the management of wounds. It is, therefore, very refreshing to note the manifest great interest in a subject that has perplexed surgeons ever since the humblest beginnings of their craft.

The vagaries of infection to which so many of the speakers alluded, are matters with which every one is familiar. We have all had ample opportunity to note how the mortality of pneumonia, empyema and other infections has varied from year to year independent of the mode of treatment employed. Obviously, therefore, it is an item to be reckoned with in evaluating the results of any scheme of treatment.

It is important that surgeons review critically the remedial measures which they employ in the treatment of infection. It is so easy to continue indefinitely with therapeutic agents which have not proved their worth. Surgeons generally have come to recognize their own great shortcomings in dealing with spreading infections. We no longer see surgeons making incisions in phlegmonous inflammations in the hope that they can thereby localize the infection. They have come to know that only the natural defense mechanism of the body can do that. All the surgeon can do, apart from assisting the body in its conflict with infection, is to evacuate an abscess when localization of the infection and suppuration have occurred.

I have had no experience with the conservative means of management here described in impalement types of injury which result in rapidly spreading infection and bacteremia. Instances are known to all of us in which extremities have been uselessly sacrificed in the hope of stopping the centripetal spread of the infection. The experiments of Schimmelbusch (1894) with tetanus toxin and the rat's tail are undoubtedly known to most of you. He observed that, if the denuded rat's tail was immersed in a culture of tetanus toxin, when more than 10 minutes elapsed it was futile to cut the rat's tail off at the base. The toxin had already penetrated beyond. I am inclined to believe that the interests of patients who suffer impalement types of injury giving rise to virulent infections, are better served by conservative means. Friedrich (1898) was able to show that the immediate application of antiseptics and employment of excision to tissue did exert an important influence when applied early in experimental infections in which dirt had been rubbed into wounds. After the lapse of six hours, the employment of such expedients was without value. His experiments constitute the basis of the modern débridement of soiled wounds.

The great value of immobilization and elevation in the treatment of pyogenic infections of the soft parts can be appraised now. He who will give the method a trial will observe that pain will decrease and that swelling lessens. The necessity for incision for the evacuation of exudate is less than with employment of hot fomentations with the extremity upon the bed slightly below the level of the heart. The results of treatment of acute hematogenous osteomyelitis in the manner described above must await the lapse of a sufficient interval of time. It has been intimated that the satisfactory results attending conservative treatment of acute osteomyelitis may have their explanation in rather benign forms of the disease. I value that suggestion, for an observer must always be on the alert lest he deceive himself. Yet, I would again say that many of these patients with osteomyelitis herein referred to were very ill. During the same period we have seen a few patients who had their trepanation before they came to us. The early effects, i.e., healing of the wound and subsidence of the inflammatory

(Continued on page 78)

TRANSACTIONS of the MINNEAPOLIS SURGICAL SOCIETY

Meeting of November 4, 1937

The stated meeting of the Minneapolis Surgical Society was held Thursday, November 4, 1937, the president, Dr. O. W. Yoerg, in the chair.

The following papers were presented:

CARCINOMA OF THE GALLBLADDER WITH IMPLANTATION IN THE ABDOMINAL WALL

Case Report

James A. Johnson, M.D.

MRS. D. W., aged seventy-three, was admitted to the Eitel Hospital October 7, 1936. Her previous history was negative except that she had a gallbladder drainage ten years ago, at which time stones were removed. She had been well until August 15, 1936, when she had an attack of vomiting which she attributed to a dietary indiscretion. On September 1, she had another attack of nausea and vomiting. There was no pain with either of these attacks. Two days after the last attack her daughter noticed that her eyes and skin were yellow. The jaundice gradually became more pronounced and she had intense itching all over the body. Her appetite had been poor and she had lost 8 pounds in weight. She consulted her family physician, Dr. S. Ericson of Le Sueur, Minnesota, who referred her for examination and also thought from his observation that there was a possibility of stone in the common duct.

Examination revealed a poorly nourished, viscer-optotic, feeble old lady. The abdomen was moderately distended. The liver was smooth and extended three fingers below the right costal margin. She was deeply jaundiced. The urine was loaded with bile pigments. Exploratory operation was advised.

At operation October 9, 1936, the gallbladder and duodenum were found buried under omental adhesions. Four large stones were removed from the common duct and three stones from the right hepatic duct. The gallbladder was opened, no stones were seen, and the mucosa looked normal. The pancreas did not feel hard. The stomach and duodenum were normal. The liver was engorged with bile. A T-tube was placed in the common duct and the gallbladder was drained. Because of the extreme enlargement of the liver both drains were brought through the lower angle of the wound just inside the iliac crest.

The postoperative course was uneventful. The jaundice promptly disappeared, the liver receded to its normal size, she ate well and gained her normal weight, and continued in good health until the middle of July, 1937, when she began to have gastric distress with occasional vomiting. This increased until she was unable to retain any food. She was again admitted to the Eitel Hospital August 18, 1937. A barium meal demonstrated an obstruction at the second portion of the duodenum. At the lower angle of the scar—the site of the previous drainage—there was a hard nodule about 3 cm. in diameter.

At operation August 21, 1937, incisions were made through the old scar, and the nodule was removed separately. It was hard and on cross-section looked like a carcinoma—resembling a scirrhus carcinoma of the breast. It was confined to the tissues of the abdominal wall and did not invade the peritoneum. A microscopic examination was requested. On opening the abdomen the duodenum and omentum were firmly fixed underneath the liver, as if there had been a perforation. When the duodenum was separated, a necrotic perforation was present which was sutured with dulox catput, and a posterior gastroenterostomy was done. The gallbladder and pancreas could not be visualized or palpated because of the large inflammatory mass which was thought to be due to the perforation. Following operation a microscopic section of the nodule by Dr. Koucky showed a fibrous tissue stroma within which were imbedded malignant carcinoma cells. Evidently the malignant cells had been carried through the drainage tube and grown by implantation in the abdominal wall.

After the operation she developed leakage from the duodenum, which resulted in peritonitis, and death occurred on the seventh day.

Postmortem.—The gallbladder was completely replaced by a white tumor mass. There was a metastatic mass on the posterior surface of the right lobe of the liver near the vena cava. The lower end of the common duct, head of pancreas, pylorus and duodenum were imbedded in a solid mass of fibrous tissue. There were small seed-like implants along the root of the mesentery and posterior abdominal wall. Microscopic examination showed primary carcinoma of the gallbladder with metastases to the liver and peritoneum. The pancreas was free.

There was a bilateral terminal bronchopneumonia.

Comment.—The extension of carcinoma from its primary focus is usually by the lymph vessels or by direct extension. A less common, but nevertheless definite, method is by direct implantation of the cancer cells at sites distant to the original tumor. In this case the cancer cells evidently were carried directly through the drainage tube into the abdominal wall, where they began to grow and formed a separate distinct tumor. There are several well-known examples in which carcinoma spreads by implantation. It is common, for instance, when a carcinoma is present in the stomach to find implant growths deep down in the pelvis. Likewise, in primary carcinoma of the ovary, it is common to find it spread uniformly throughout the abdomen in the form of miliary nodules. The cells evidently spread through the peritoneal fluid; occasionally also into the abdominal scar. It is uncommon, however, to find so striking a case as the above, where the carcinoma cell has implanted itself in entirely a different tissue at a remote distance from the original lesion. This brings us to the importance of such a clinical finding. It seems to me that it is evident that a surgeon must be careful when operating upon cancer not to invade the growth or glands in such a way that the loose implants are scattered in the healthy tissue. This is especially important for example when doing a biopsy on the breast. Here the tissue should be widely excised and gloves and instruments discarded before proceeding with the radical operation. It is also important in removing the involved glands not to macerate them and infect surrounding tissues.

My purpose in reporting this case is to stimulate an

interest in clinical evidence of cancer implants and the benefit we may derive from it. I hope members of this Society will be looking for similar cases and report them to us.

Discussion

Dr. George D. Eitel: Statistics indicate that 5 to 7 per cent of all carcinomas found at necropsy originate in the gallbladder. There is also a definite association with gallstones, and different reports indicate their presence in from 65 to 90 per cent of cases. It is more common in females and usually occurs between the ages of fifty and sixty. Walters, in 1936, reported thirteen malignant gallbladders in 808 cholecystectomies while Judd, in 1931, reported twenty-two cases in 879 cholecystectomies.

The diagnosis is usually not made except in advanced cases when the patient is very ill, usually jaundiced and presents a palpable tumor. In the earlier stages of the disease the diagnosis is usually a nonfunctioning gallbladder with or without stones. Because the lesion usually originates in the cystic neck of the gallbladder, there is always an obstruction to the entrance of the gallbladder and x rays fail to depict the lumen of the gallbladder.

Kirklin reports sixteen cases of carcinoma of the gallbladder in which cholecystograhpy preceded the operation, and it was found that in fourteen cases no shadow of the gallbladder appeared although gallstones were present in seven. In one case function was present but multiple stones were present and in one the shadow was normal.

The gross pathology is usually an irregular carcinomatous mass involving the wall with a stone or multiple stones in the center—probably the source of the original irritation. Perforation of a carcinomatous gallbladder rarely occurs, but when it does, secondary growths occur causing ascites or a fistulous opening between the gallbladder and a hollow viscus.

The common mode of extension is to the adjacent liver either directly or through the blood vessels or to the lymphatic glands lying in the hepatic fissure.

At operation those readily recognized as malignant are usually irremovable. Death is usually caused by hepatic insufficiency, or if removal or even biopsy is done, death may result from an associated severe hemorrhage.

The permanent cures of carcinoma of the gallbladder are usually those in which the gallbladder is removed for a chronic condition and the routine laboratory miscrosopic examination of the gallbladder disclosed malignancy.

The microscopic pathology is usually adenocarcinoma, although in a series of thirty-three cases careful studies revealed the presence of squamous cell carcinoma in three cases. Kaufman reports a case of sarcoma and states that only thirteen cases are on record.

Dr. Kenneth Bulkley: Might I ask the reader or his discussor as to the radio-sensitivity of these recurrences?

Dr. James A. Johnson: Dr. Bulkley asks about the sensitivity of carcinoma of the gallbladder to x-ray treatment. I am unable to answer this question directly since our experience with carcinoma of the gallbladder is rather limited. I would say in a general way, however, that it would react unfavorably because as a rule this is true of carcinoma of any of the abdominal organs.

I want again to summarize the important finding in the case just reported. At the time I first operated upon this woman, removing the stones from the common and hepatic ducts and draining the gallbladder, I was unable to find any evidence of carcinoma. She was entirely well for about one year, when she returned with an obstruction of the second part of the duodenum. The main finding, however, was a nodule which was present in the abdominal wall and was confined to the skin, fat, fascia and muscular tissues, and did not involve the peritoneum. Since it would be impossible for this to be transmitted through the blood or lymph channels, it is certain that this could only arrive through a direct transplant. The primary carcinoma was in the gallbladder and the carcinoma cells evidently drained through the drainage tube directly into the abdominal wall where they began to grow. I believe this is a significant finding.

DIVERTICULUM OF THE ESOPHAGUS

A. A. Zierold, M.D.

SOMETHING over a year ago this man was sent to me complaining of gurgling and a fullness in his neck and regurgitation of food. These symptoms had persisted over a period of ten to fifteen years, increasing to a point where he was having definite distress. The regurgitation was becoming not only embarrassing but was interfering with eating. X-ray examination revealed an esophageal diverticulum which, peculiarly enough, was in the midline. These pulsion diverticula (this discussion will be confined entirely to pulsion diverticula), are herniations of the mucosa and submucosa through the musculature at the junction of the lower portion of the pharynx and the beginning of the esophagus, forming a sac which descends usually on the left side of the neck, increasing in size, so that the esophagus is deflected to one side, making the esophagoscopy or the passage of a Bougie dangerous.

In the past, any treatment directed toward the correction of this has been attended by considerable danger because of the difficulty of removing, ligating, or suturing such a wide mouthed sac and preventing leakage into the mediastinum. The diverticulum passes downward between the prevertebral and pretracheal fascia and affords direct access to the mediastinum and any leakage is very promptly followed by a mediastinitis. In the past, attempts were made to excise the sac, exposing the sac and suturing it. The major danger was, of course, the leakage and the mediastinitis which followed. The second complication which often followed was a constricture of the esophagus. This state of affairs continued until such time as the two-stage operation was devised in which a preliminary operation for the exposure of the sac was performed. The sac was identified, dissected free and the mediastinum was walled off by adhesions between the fascial planes. At a later date an attempt was then made to tie off or suture the sac. This, while an improvement, was not entirely successful.

I am presenting this patient to you this evening to illustrate how a formidable procedure can be made easy. Dr. Lahey, I believe in 1930 or 1931, devised a method which is as near fool-proof as any and is the best example of surgical ingenuity and clear thinking

that I know of. I don't know when I have seen or when I have done anything that has given me so much pleasure as Dr. Lahey's technic for the cure of esophageal diverticula. Dr. Lahey advises a longitudinal incision along the sternomastoid, retracting the sternomastoid together with the carotid sheath and the large vessels. Then, by ligating the lateral thyroid veins and the inferior thyroid vessels, direct exposure is afforded of the esophagus and of the diverticulum which, of course, begins at this point and extends downward. It is surprising what a bloodless field and what a really accessible field can be obtained with so little dissection. When this is done, the sac is carefully dissected free, remembering, of course, that it is only submucosa and mucosa. Care is taken to free the attachments at the lower angle and to reverse the angle of the sac, bringing it up to an obtuse angle and suturing the sac to the skin. That is all that is done at this operation. Care is taken, of course, to dissect well around to the right side to free any adhesions occurring on the opposite side. The fundus is sutured to the skin edge and is allowed to remain there, as in this case, eight days.

At the end of that time the end of the fundus is cut off level with the fascia and the mucosa which lines the diverticulum is separated from the submucosa as far as the esophagus. It is then cut off at a point one inch from the neck of the sac and folded upon itself. This tube of submucosa is loosely filled with some vaseline gauze. The mucosa very promptly retracts and contracts until it eventually gives a smooth lining to the esophagus. The submucosal tube becomes obliterated and at no time is there an opening or communication between the esophagus and the wound. At no time is there an opportunity of leakage into the mediastinum. In this instance, happily, there was no drainage after the second operation, no regurgitation of food and no fluid discharge through the sinus. At the end of another ten days the patient was discharged. He has had an uneventful convalescence and I present him to you this evening to show you that the residual submucosa causes no contraction deformity of the scar in the neck. It is freely movable in all directions. The patient has been symptom-free up to the present time. The only thing we haven't done is to dilate him postoperatively. Dr. Lahey advises the routine dilation of the esophagus on the assumption that the initiation of the diverticulum is due to a spasm of the beginning of the esophagus. In this instance the patient apparently successfully survived the interval and I see no reason why he should not continue.

Discussion

Dr. Orwood J. Campbell: I envy Dr. Zierold for the pleasure he must have had in caring for this patient. My own experience with the surgical treatment of diverticula of the esophagus has been very limited but the few operations for diverticula which I have done have been fun and I have enjoyed doing them.

Dr. Lahey has described an ingenious operation the principal advantage of which is that it provides a tube whereby any leakage from the esophagus is transported to the outside and not permitted to escape into the fascia layers thus to produce a mediastinitis. In some of these sacs I should anticipate considerable difficulty in shelling out the mucous membrane because of inflammation and adhesions. In such a case it would be a simple matter to do the classical two-stage resection removing the entire sac.

The principal controversy today among those who see many of these cases seems to be whether the operation shall be done in one or two stages. Dr. Jackson and his associates advocate the one stage procedure, using the esophagoscope as an aid.

The esophagoscope is passed into the diverticulum and its contents aspirated. A strong light on the end of the esophagoscope then transilluminates the sac and makes it easy for the operating surgeon to locate, free and deliver the sac into the wound. The sac is then excised and with the esophagoscope passed on down toward the stomach primary suture is done.

My limited experience does not warrant my advocating one or the other method. Personally, I like the added protection of the two-stage operation. Especially is this true if the sac is large. Smaller diverticula may be closed primarily.

Dr. Zierold mentioned narrowing of the esophagus as a complication of the usual two-stage resection. Judd, in reporting his experience with 171 operated cases, did note a small percentage of narrowing of the esophagus but stated it had not been a serious difficulty. They do not make a practice of dilating the esophagus except when indicated.

I believe the use of the esophagoscope even in the two-stage operation of resection has definite advantages. It will assist the surgeon in locating the sac and at the second stage, can be passed on down toward the stomach to prevent narrowing of the lumen when the neck of the sac is sutured. If this precaution is observed I believe a troublesome narrowing at the point of suture can be avoided.

Dr. S. R. Maxeiner: In our service at the Veterans' Hospital we have had two cases of esophageal diverticula in the last two years. Upon the first patient we performed the two-stage procedure, bringing the sac into the elevated position along the pharynx at the first stage and ten days later resected the sac. The neck of the sac was tucked beneath the muscle planes which were closed tightly. In this case healing progressed without infection and with a perfectly normal convalescence.

The second case was operated upon by Dr. Sedgely and myself by one-stage technic which I suggested and which I have not seen described any place in the literature.

Technic.—A customary incision was made along the anterior border of the left sterno-mastoid muscle. The inferior thyroid artery was ligated and the muscles and the vessels retracted laterally and the thyroid retracted medially. The sac, which was of good size, was dissected free until the pedicle was well exposed, the muscle planes were separated well back from the mucosa and a small curved forceps was placed across the pedicle close to the lateral wall of the esophagus. A second forceps was placed across the pedicle of the sac parallel to and a short distance from the first pair of forceps. The pedicle was divided between the forceps with a cautery knife and the second forceps together with the diverticulum was removed. The muscle planes were then carefully sutured over the forceps which was clamped to the cut-off end of the pedicle so that all of the forceps containing pedicle was completedly buried by the overlapping muscle planes. The wound was then loosely closed around the forceps, which was left in situ to act as a drain. On the seventh day the forceps became spontaneously

detached and fell out. There was a very small leak of a few drops of clear fluid which drained out of the sinus established by the forceps for approximately a week. The wound healed uneventfully and the patient made a splendid recovery.

The object of the two-stage operation is primarily to prevent mediastinal infection. We believe that the forceps establishes a definite sinus with the walling off of the fascial planes before the forceps separated and a leak occurs as was proven in this case. We feel that this technic in this one case proved to be entirely satisfactory and efficient and is certainly deserving of further trial.

Dr. James A. Johnson: It has been very interesting to listen to Dr. Zierold's report of removal of this esophageal diverticulum. It has been my custom to remove these diverticula in two stages, and following the second stage I have been in the habit of putting in a nasal tube for feeding purposes and to also obviate any possibility of vomiting for a few days until healing has taken place. I would like to ask Dr. Zierold what his postoperative care was in this particular case.

Dr. A. A. Zierold: I did not restrict him at all. He went on a general diet forty-eight hours after the resection.

ENDOMETRIOSIS

William R. Jones, M. D.

ENDOMETRIOSIS is the presence of endometrium outside of the uterine cavity. Its cause is not definitely known. However, there are several theories as to its origin. Those most widely recognized are: (1) the implantation one of Sampson, who believes that endometrial tissue finds its way through the fallopian tubes into the abdominal cavity where it implants itself and grows; (2) the embryonic rest theory advocated by Cullen and others. These men believe that the embryonic rests are activated during active menstrual life and give rise to symptoms.

Endometrial growths are found in the abdomen and pelvis from the umbilicus downward. Most frequent locations are the uterus, fallopian tubes, ovaries and the recto-genital space. Less frequently they are found in the rectum, intestines, sigmoid, appendix, vagina, uterine ligaments, umbilicus and abdominal scars following operations on the uterus.

The essential pathology is a menstruating endometrium within a closed sac and the complications of this process. The growth may vary from the size of a millet seed to a mass as large as a six months' pregnancy. As the mass enlarges it tends to infiltrate the host tissue. No definite line of cleavage is present. When the ovary is involved the cyst may rupture and a dark chocolate colored material escapes into the abdominal cavity. This material is highly irritating and stimulates dense adhesions between tissues that it contacts. These adhesions are very difficult to separate as they are infiltrative in type.

Microscopically the growth resembles endometrium very closely. Endometriosis usually occurs between thirty years of age and the menopause. According to Sampson, it is present in from 10 to 20 per cent of women. The outstanding symptom is dysmenorrhea of the acquired type. Usually the first symptom is severe abdominal pain at the menstrual time which is most frequently lower abdominal, but may be upper abdominal or over the entire abdomen. The pain will last throughout the menstrual period, differing from that of cervical stenosis, which usually decreases after the flow has started. There may be some constant abdominal pain, but it is much more pronounced at the menstrual time. Nausea and vomiting may occur, suggesting acute appendicitis. If a chocolate cyst ruptures into the abdominal cavity, there will be signs of peritoneal irritation, nausea, vomiting and boardlike abdominal rigidity and increased leukocyte count. If the growth encroaches on the bowel, there may be symptoms of intestinal obstruction. If on the vagina or rectum, coitus may be painful or impossible and there may be pain during the act of defecation.

The treatment is surgical exploration and removal of the growth with conservation of the ovaries, if possible, in young women. In older women, both ovaries should be removed as this stops the progress of the disease and also causes a regression. For the recurrent cases and irremovable growths, sterilization by x-ray or radium is a treatment of choice.

Case 1.—The first case is that of a woman twenty-nine years of age. This patient was admitted to the Eitel hospital, January 9, 1937. She complained of severe lower right abdominal pain. There was no nausea or vomiting but the patient had lost her appetite. Her past and family histories were negative. Examination revealed an obese young woman, evidently suffering severe pain in the abdomen. There was marked tenderness and rigidity in her right lower abdomen.

Pelvic examination was negative, except tenderness on palpation. The white blood count was 16,000; polymorphonuclears 80 per cent. The urine was negative. A diagnosis of acute appendicitis was made.

Exploration of the abdomen revealed a leaking chocolate cyst of the right ovary. The entire ovary seemed to be involved and therefore was removed. The left ovary appeared to be normal. The patient had an uneventful recovery and seemed to be well for four months. Then she began having pain with each menstrual period. The past three periods have been so painful that morphine was required for relief. This patient has been advised to have x-ray treatment.

Case 2.—The second case is that of a nurse thirty years of age. The family history was negative. She had been treated for kidney stones in 1927. Her appendix was removed several years ago. She was seen by me at her home November 29, 1929, because of severe abdominal pain which began after her menstrual period started. The pain was followed by nausea and vomiting.

The patient stated that she had a similar attack in June, 1929. Severe abdominal pain was present, which appeared on the third day of her menstrual period. Her temperature at that time was 103° and leukocyte count was 16,000. She was confined to the hospital for five days. Her physician made a diagnosis of peritonitis. The July and August menses were normal. However, in September, on the third day after she began to flow, severe generalized abdominal pain again oc-

cured, which lasted until she stopped flowing. In October she experienced the same difficulty.

Examination, November 29, 1929, showed a well developed young woman evidently suffering severe pain. Her abdomen was very tender and rigid. Pelvic examination caused pain, but no abnormal pelvic masses could be palpated. The patient was taken to the Eitel hospital and a consultation was held with a gynecologist and urologist. Under ether and anesthesia, pelvic examination revealed a mass in the right adnexal region. Exploration was advised and was done.

When the abdomen was opened a cyst of the right ovary, the size of a small orange, was found, from which dark chocolate colored material was leaking. There was an unruptured cyst of the left ovary the size of a hen's egg. Because of the patients age, a conservative operation was decided upon. The cysts of both ovaries were removed and the ovaries recon structed. There was nothing unusual about her convalesence. Four years later she married and moved to another city and has not been heard from since. For these four years she was free of symptoms.

Discussion

Dr. Richard R. Cranmer: To me, endometriosis is a very unusual and peculiar condition. It has some of the earmarks of malignancy but still it is not a malignancy. The man who made a comprehensive study of endometriosis first was Sampson in 1921 and he advanced certain theories as to its etiology. He outlined, or rather, classified the different types according to the method that the endometrium reaches its ectopic positions. His first classification is that of primary endometriosis, where the endometrial cells misplaced in the uterine body develop that condition commonly known as adenomyoma and which penetrate the entire thickness of the uterine wall. Sometimes these adenomyomata, that are of mucous origin and definitely secondary to an extension process of the endometrium, are found out underneath the peritoneum, indicating that they can travel. The second classification is the implantation classification in which the endometrium is forced out of the uterine cavity through the tubes and into the peritoneal cavity and there it becomes an implant and develops and grows. Not only is it activated by the hormones just as the endometrium of the uterine cavity is, but after it has reached its location it develops and grows in size just as a malignancy does. That is the common type of endometriosis, the kind that we see most of, and it is that type that produces the so-called chocolate cyst of the ovary. The third classification is where the endometrium is transplanted into new locations due to operation. Sometimes it develops in the abdominal wound and sometimes in the perineal wound. A fourth classification, according to Sampson, is where the endometrium cells do have a metastatic action and cause metastasis into other areas in the pelvis, not in the peritoneum but in the subperitoneal areas.

Sampson also admits the possibility of endometriosis being due, in some instances, to misplaced endometrial tissue in the Wolffian body. He said he had never had any cases that he thought developed in that way but he admits the possibility of it.

As far as the treatment is concerned, Dr. Jones has covered that; the prophylactic treatment is to prevent those things which cause an expression of the endometrial cells through the tube and then into the peritoneal cavity. Sampson thinks that the inflation test of Rubin for determining the patency of the tubes should not be done soon after menstruation. He recites a case where some of the implants developed following such a procedure. Curettage soon after menstruation is also advised against.

As far as the operative treatment is concerned, he thinks that if it is a young woman with a single ovary involved, the ovary should be removed but not the other ovary. If it is a widespread process the best thing to do is double oöphorectomy and possibly a panhysterectomy. Then, if all the implants cannot be removed, radio therapy should be used. However, there is an argument against the use of the x-ray because usually in this condition there are a lot of adhesions and the x-ray increases adhesions and might increase the symptoms resulting from them. There are very interesting cases reported. Dr. Ikeda, St. Paul, reported a case the other night. The patient was being operated on for suspected appendicitis and the patient had, implanted on the appendix, a section of endometrial tissue which evidently was the cause of the trouble. Dr. Gingold reported a case where the body of the uterus was involved and multiple implants were on the peritoneal covering of the uterus. In that case he did a panhysterectomy besides a double oöphorectomy. I think we have all seen chocolate cysts. At Asbury Hospital the pathologist told me that fifteen cases were operated upon in the last year and I would estimate probably 125 or 150 are operated upon each year in Minneapolis.

An interesting experiment was done on the eye of a monkey by Cullen. Endometrial tissue was implanted in the anterior chamber and its development was watched. It was found that blood appeared in the anterior chamber about three hours before menstruation, indicating again that this misplaced tissue does respond to hormonal action even though remote from its original position.

Dr. T. H. Sweetser: I wish to add to the discussion the observation that the ureter is quite liable to damage during operations for endometriosis in the broad ligament. The margins of the endometriosis are ill-defined, hemorrhage is liable to be quite troublesome, and in dissecting down to the lower margin of the hemorrhagic tissue one reaches the plexus of veins at the side of the cervix and is quite liable to clamp the ureter. I have recently been asked to examine urologically one patient whose ureter had been thus damaged with resultant suprapubic urinary fistula. Nephrectomy was finally necessary to obtain a cure.

TERATOMA OF THE TESTICLE: HINMAN OPERATION

Report of a Patient Cured Four and One-half Years Following Radical Surgery Removal

Lawrence M. Larson, M.D., Ph.D., F.A.C.S.

In the treatment of malignant tumors of the testicle, one has at his disposal three methods. These are as follows:

1. Simple castration.
2. Radical operation in which the testis and its lymphoglandular drainage areas are removed.
3. Roentgen therapy either alone or in combination with the above described methods.

Regarding the first possibility, namely simple castration, it is evident that this method of treatment is not in accordance with the principles of surgery of cancer as applied to other parts of the body. No account is taken of the fact that these tumors commonly metastasize early into the retroperitoneal and aortic region and cure of this lesion cannot be expected in any large percentage of cases without removal of these lymph-bearing tissues.

The second method, radical operation in which the testicular tumor along with the lympho-glandular drainage area is removed at the same time, is a procedure which should and does give much better end results. This has proved to be the case, according to statistics, in a large number of individuals who have been operated for this disease. Furthermore, radical operation such as that recommended by Hinman is not much more dangerous than simple castration and experience has likewise shown that the technical difficulties are not great. The lymphatic drainage area of the testicle has been carefully worked out so that it is possible to excise with anatomical accuracy the region in which metastases are known to occur.

The third possible method of treatment has probably the most to recommend it of any of the other methods. Roentgen therapy in combination with surgical excision of the tumor has proved to be unusually efficacious in a certain group of these tumors, since it is a well-known fact that some of them are highly radio-sensitive. Roentgen therapy alone should probably be reserved for those cases in which it is possible to demonstrate clinically the presence of metastases in the regional lymph nodes. At any rate it is no doubt better to use this combined method in most cases.

Hinman, in 1933, reviewed a large number of cases of malignant testicular tumors with the purpose in mind of determining end results and found that approximately 15 per cent were cured by simple castration, and there were 30 per cent cured by the radical excision of the tumor with its lymph drainage area. The most favorable group of cases he found were those in which no metastases were demonstrable and in whom radical operation was done. Of this group of thirty-six cases, eighteen were living and well four years after the operation. Thus it is evident that even if no metastases are demonstrable clinically, radical removal of the lymph-bearing fascias is certainly worth while.

Pathologically, tumors of the testis are usually divided into two types, the seminoma and the teratoma. Both are highly malignant. They metastasize early to the primary lymphatics as well as to the lungs, liver and other organs. The immediate type of cell in these tumors still remains uncertain although the origin may be the connective tissue, the epithelial tissues or there may be a mixed type of tumor having components of both. Regardless of the origin of these tumors they must all be regarded as malignant. Clinically they all act similarly. The seminomas have been said to be more radio-sensitive than the teratomas, but this is not a constant observation so that roentgen therapy should be used in most of them either alone or in combination with surgical excision.

This patient was nineteen years of age when first seen in May 1933. He had always been in excellent health and had had no operations except for tonsillectomy in childhood. The history of his present illness goes back three or four months when he first noticed enlargement and pain in his left testicle. These symptoms gradually increased in severity although at no time did he notice any loss of strength. He had had no loss of weight and by wearing a suspensory he has been entirely comfortable. During this four months period he thinks the left testicle had slowly and gradually enlarged but he paid little attention to it.

Physical examination: He is in apparent good health. He is five feet eleven inches tall, weighs 170 pounds, his color is good, and his muscles were all in unusual excellent condition. His entire physical examination was negative except for the left testicle. The latter was two to three times normal size and was surrounded by a fluctuant sac which apparently contained a small amount of fluid. Through this sac could be felt an ovoid tumor which involved the entire testis. The outline of the tumor could be distinctly made out and it was quite smooth with the exception of a few irregular areas in the upper and medial portions. The consistency of the mass was very hard and it was freely movable within the sac. It was not especially tender. The mass did not transmit light and no fluctuation could be made out. The epididymis could be distinctly made out in its usual position and the spermatic cord with the vas deferens could be readily palpated. The skin of the scrotum was freely movable throughout.

June 3, 1933 operation was done under gas anesthesia. A high left inguinal incision was made, the testicle delivered from the scrotum and simple castration was done. The spermatic cord was divided between clamps by cautery after it was dissected free, and the clamp was left on the proximal portion of the cord for traction. Immediate frozen section of the tumor mass was made and the report by the pathologist showed it to be a highly malignant teratoma. The patient was then placed partially on his right side and partially on his back, somewhat similar to the position for exploration of the kidney except the position was a bent dorsal-lateral one. A pad was placed under the left costal margin and the left knee and hip were slightly flexed with the right leg straight. The incision was then extended upward so as to follow the course of the iliohypogastric and ilioinguinal nerves, thus avoiding cutting them. It was carried as high as the tip of the 12th rib to which it ran somewhat parallel. The fascia of the external oblique muscle was next divided starting from the external ring and the muscle bundles then split as they paralleled the course of the incision. The internal oblique, the transversalis, and the latissimus dorsi muscles were divided also in the line of the incision. The ilioinguinal and iliohypogastric nerves were carefully avoided. The peritoneum was next encountered. Beginning in the iliac fossa this was retracted medially stripping it as far as the iliac vessels and the bladder. Here it was necessary to carefully avoid carrying the spermatic vessels and the ureter along with the peritoneum. These structures should be left behind on the surface of the psoas muscle. The spermatic cord was isolated and traction put on it so as to facilitate this dissection.

The vas deferens was then divided where it disappears behind the bladder. Next the peritoneum was further stripped back so that the iliac vessels and the aortic bifurcation identified, thus further exposing the retro-peritoneal tissues. The ureter was carefully avoided overlying the psoas muscle and the peritoneum stripped away as high up as the renal pedicle. The peritoneum was then pulled laterally and maintained in this position by retractors. The lymphatic tissues were then removed from the iliac vessels about the aortic bifurcation and along the preaortic area. There was a considerable mass of lymph tissue in this region extending up as high as the kid-

ney pedicle. A few small metastatic glands were encountered along the aorta and trauma to these tissues was avoided. The spermatic cord along with the lymph-bearing tissues described were then removed in one piece. Traction on the clamp attached to the spermatic cord was of considerable help in identifying the tissues to be dissected. Drainage of this large lymphatic area was then made by means of several Penrose soft rubber drains through the lower angle of the wound. Closure of the muscles in the lower part of the incision were made as for hernia.

The tumor measured 8x7x4 centimeters in diameter and it was solid yellowish in color with a few small cystic areas. The tunica vaginalis and the epididymis were not involved and could be identified. There was a small amount of compressed testicular tissue at the lower pole of the tumor and a number of hemorrhagic areas throughout the mass. Microscopically the cells resembled those of carcinoma interspersed with lymphoid stroma. There were many areas of necrosis and hemorrhage and a few smooth muscle bundles could be identified. The diagnosis was teratoma of the testis.

The postoperative course was uneventful. The incision drained considerable serum for about ten days and on the fourteenth day the patient was allowed to go home. As an additional therapeutic measure roentgen therapy was instituted three weeks postoperatively by Drs. Allison and Hanson, who gave him large doses over the entire lower abdomen. About six months after the operation he joined the Civilian Conservation Corps where he stayed in a camp in Northern Minnesota for a year and did all the hard work that was required of him. His strength since the operation has returned to normal. After leaving the CCC's he obtained work as a mechanic and has continued this work since without interruption. He has been examined about twice yearly since the operation, the last time two weeks ago, and at no time has there been evidence of recurrence or metastasis of the tumor.

Discussion

Dr. Gilbert Cottam: Dr. Larson has entered into the technic of the operation so thoroughly that it is unnecessary to deal with that phase of the subject. I would like to say a few things about the incidence of these tumors. The experience that any one of us has is so slight we cannot talk of any statistics derived from our own work. Probably only a half dozen men in this room have ever seen a teratoma of the testicle but any one of us may see one tomorrow morning. There are two things that I think we might consider in regard to the matter of the rarity of them and the only way we can get at it, of course, is by the aggregate experience of others. Hamilton Bailey of London has recently published a monograph which is highly valuable in this connection; it is a compact little work in which he has dealt quite freely with the statistical side of this subject. I will take the liberty of quoting one or two things that he mentions which I think are very interesting. From a large number of assembled individual cases he has arrived at the conclusion that 58 per cent of all malignant tumors in the male are of the testicle but, on the other hand, the Mayos have seen, in nine years, 155 cases so you see in a large volume of work like they have one runs against a fairly large number of cases.

Teratomas, according to another set of statistical figures, constitute about one-half of the malignant tumors of the testicle. The other half are carcinomatous seminomas which the French observer, Chevassu, has described and named; and one per cent are sarcomas.

In the diagnostic field there is one feature that is dwelt on particularly and that is the early rapid growth of teratomas as compared with carcinomas. The estimate is made by Bailey that when a man develops a teratoma, he is apt to come in for medical advice within six months after he has first noticed it, whereas in a carcinoma the interval is apt to be a year.

As regards metastasis, an American observer, Ferguson, has collected sixty-nine cases and he has found metastases in the supraclavicular nodes in six, in the mediastinum in eleven, in the pulmonary lymph nodes in thirteen and in the epigastric in thirty-nine. The operated percentage, Dr. Larson mentioned. Hinman had 100 cases but in the case of that one patient who died, it really was not an operative death. He died on the tenth day of pneumonia.

Now, what is the prognosis? Here again we come back to Hinman and we find, of the radical cases, his own operation, out of eighty traced cases, seventeen were alive after five years. In simple orchidectomy, with or without irradiation, 258 cases have been collected. Of these, only seventeen were alive after five years, so you see the percentage of good results appears much greater in the Hinman operation. Yet, I am told, Hinman himself is now lukewarm about his own operation, in view of the early and unpredictable metastasis to the opposite side in so many cases.

Dr. Kenneth Bulkley: At fairly regular intervals this question of malignancy of the testicle comes up and I never miss the opportunity to get up and bring up to date a case which I think has finally become rather well known in medical literature.

This case I reported originally in 1911 in *Surgery, Gynecology and Obstetrics*. It was that of an individual in the early forties whose wife had been repeatedly examined for sterility. No one had ever thought to examine him, although it turned out that he was a double cryptorchid. The man accidentally, while bathing, discovered a lump in his left lower abdomen. He was seen by Dr. Joseph A. Blake, recently deceased, and was operated upon by him in 1911, a large malignant intra-abdominal testicle adherent to small gut being found. A simple orchidectomy was done with removal of about a foot of small intestine with end-to-end anastomosis. No radical gland dissection was done, yet this man remained alive without further difficulty of any sort until about three years ago when he died from other causes. In those days deep x-ray therapy was unknown and this individual received no treatment whatsoever other than local excision. The excised testicle was pronounced by Dr. James Ewing to be a teratoma. In other words, this is a case of a malignant intra abdominal teratoma of the testicle which received a local excision only, no gland dissection, no deep therapy and yet the patient lived for some thirty years.

There are a number of points in regard to intrascrotal masses which I believe should be brought out in this discussion. The diagnosis is, of course, important and is not always easy, inasmuch as in a case I operated on only a few days ago, the mass may prove not to represent a testicular malignancy but an old hydrocele with walls so thick that transillumination is impossible. Tuberculosis also must be thought of and of course syphilis of the testicle. As far as the type of malignancy is concerned, I cannot help but be convinced that all malignant tumors of the testicle represent teratomas. This was first brought out by Ewing. In the particular case to which I referred at the beginning of this discussion, some ten or a dozen blocks were made, all of them showing apparently a pure sarcoma. However, with the cutting of more blocks different types of malignancy were encountered showing the case to be one of a teratoma.

There is just one other point which I would like to emphasize, chiefly because it sustains the thesis that radical gland dissection is inadvisable and unnecessary.

It is not uncommon for an individual to present himself for examination totally unconscious that anything wrong within his scrotum is the cause of the mass in the left supraclavicular region. When the man so presents himself always examine carefully the contents of the scrotum. Sooner or later the vast majority of cases of a malignancy of either testicle present a metastatic node above the left clavicle. I have never seen or heard of one appearing on the right side. It is probably due to lymphatic drainage and the position of the thoracic duct on the left.

Summarizing this discussion I would like to emphasize, first, the importance of diagnosis; second, the high radio-sensitivity of these tumors, rendering gland dissection unnecessary, and third, the fact that they probably are 100 per cent teratomas.

Dr. S. R. Maxeiner: I would like to add one more report of a case treated by the Hinman operation for embryoma of the testicle more than three years ago. The patient to date is apparently entirely well.

I would like to call attention to the research done by the Veterans Administration Facility at Hines, Illinois, with reference to the Prolan "A" and Prolan "B" as demonstrated in the urine by the Friedman test, and from a bulletin of January, 1934, I wish to quote as follows:

"While urine from normal males does not contain Prolan 'A' and/or 'B', urine from patients affected with teratoma contained from 50 to 50,000 mouse units per liter, depending upon the embryonal type of the tumor and the extent of the disease.

"Negative test results indicate: (1) No teratoma type tumor; (2) No active metastases of teratoma tumor; (3) That irradiation or surgical treatment of such cases has proven effective.

"Positive test results indicate: (1) Presence of a teratoma type tumor; (2) A recurrence of such a tumor; (3) Metastases from such tumor, whether the original tumor was removed or not; (4) The extent of the disease and the status in regard to treatment; (5) Serial tests at frequent intervals show the effectiveness of the treatment employed."

Our patient showed positive Friedman test before his operation. He has been given postoperative x-rays and although he has been checked regularly at intervals, the Friedman test became negative postoperatively and has remained negative to date.

TUMOR OF THE PARATHYROID WITHIN THE THYROID CAPSULE

J. M. Hayes, MD.

In presenting this case I want to apologize to the Society for not having more definite information to confirm our suspicions. This was very interesting to me and I think I learned something from it, and hope some of you may profit by our mistakes.

The clinical symptoms, both before and after operation gave a picture which I wish I had the ability to present to you. Now I feel that we had a combination of hyperthyroidism and hyperparathyroidism present. We made a diagnosis of hyperthyroidism before operation but felt we were missing something.

The patient was a female, sixty-one years old. She had been treated for heart trouble, and a suggestion of hyperthyroidism had been made. She had tachycardia, marked tremor and all the symptoms that accompany exophthalmic goiter. She had a basal metabolic rate of plus 35 per cent.

On Lugol's solution she improved very much and her basal metabolism came to normal. Dr. Graves said her blood study would suggest Hodgkin's disease or glandular fever, but no other symptoms of these diseases were present. Even after taking Lugol's solution for three or four weeks she still had extreme exhaustion and pain all over her body, and especially, in the long bones. Before operation the patient was extremely depressed, got around with much difficulty, had a stooped, rapidly aging appearance. The slightest trauma on any of her bones gave extreme pain. In addition to these symptoms, she had typical signs and symptoms of exophthalmic goiter.

The pain in her bones and extreme exhaustion even after taking Lugol's solution puzzled us even when we were ready to operate. We should have x-rayed the bones before operation but did not. In fact, it is rare that a diagnosis of hyperparathyroidism is made before the bone begins to break down.

I did a thyroidectomy on her in June, 1935. At operation the gland generally gave the typical appearance of hyperplasia. The pathologist said the gland was one of hyperplasia with some small adenomata about 1 cm. in diameter. At operation I noticed one small nodule at about the level of the entrance of the inferior thyroid artery. I didn't think much of it at the time but later I recalled this did appear much the same as parathyroid tumors I had seen. Unfortunately I had just recently listened to a surgeon of considerable experience say that parathyroid bodies did not occur within the thyroid capsule.

The sudden and remarkable change in the symptoms after operation surprised every one who saw her. On the second day after operation she said she couldn't imagine so great a change taking place in any one in so short a time. The whole picture seemed to change very rapidly. She appeared cheerful and said the pain in her bones had all gone. She said she thought she could get up then and go to work. She did go to the poles and vote just one week after operation.

I have seen this sudden change take place after removing toxic adenomata but never after operating on an exophthalmic goiter. The adenomata were small and gave no evidence of degeneration, so we did not think they could account for the toxicity. We were therefore at a loss to account for this unusual, sudden change. About six months later when Dr. Lahey published his paper dealing with hyperparathyroidism and cited a case very similar to this, I came to the conclusion we had missed something here. I went back to find the specimen but it had been thrown away. The patient was perfectly normal by this time so x-ray of her bones revealed nothing. I know I have not proven to you yet that we did have a parathyroid tumor here, but I do know if I get another patient with similar symptoms I will at least think of a parathyroid tumor. Perhaps many of our degenerative bone conditions would be picked up if we recognized these symptoms earlier.

Discussion

Dr. E. C. Robitshek: I am very happy to have heard Dr. Hayes' report of this case, because it gives me an opportunity to bring out that which I think should be emphasized regarding the early diagnosis and treatment of parathyroid tumors. I dare say, there are only a few of us who have had much experience with the diagnosis and treatment of this condition. If you will recall, it is only about ten or

eleven years ago that the first operation on the parathyroid glands was undertaken, and thus you will realize that only a short time has elapsed in which any great amount of work could have been accomplished and much further study of tumors of these glands made. Only last year Dr. Frank Lahey of Boston stated that he had seen five cases of parathyroid hyperplasia or tumors and he cited the fact that he thought he had missed the diagnosis in many cases and felt sure that many others also have had such cases pass through their hands unrecognized. Personally, I believe that one of the reasons for this lies in the fact that we, as surgeons, do not begin to think of parathyroid pathology until we meet a patient with a palpable or visible tumor or nodule in the neck, or until we find what I term the end symptoms, rather than the beginning or initial ones, and, unfortunately, it is not until we see a patient with a pathological fracture, or a bone cyst, or a Von Recklinghausen lesion that our attention is attracted to the possibility of parathyroid pathology. Therefore, I have listed a few of the initial symptoms, in accordance with their percentage, as found by Gutman, Swenson and Parsons, who, in an analysis of 115 such cases, found the initial symptoms to be pain in the back or extremities in 72 per cent, pathological fractures in 28 per cent, bone swellings in 26 per cent, disturbances of gait in 24 per cent, muscle weakness in 22 per cent, gross deformities in 19 per cent, polyuria, polydypsia and marked loss of weight in 10 per cent, renal colic in 9 per cent, and nausea and vomiting in 8 per cent. Lahey also calls attention to possible hyperparathyroidism in any patient showing progressively developing round back, so often due to decalcification of the vertebral bodies. X-ray examination of the bones, especially of the skull, the spine, sacrum and the femora, is important and helpful in arriving at an early diagnosis. The only certain criterion, however, upon which a diagnosis of hyperthyroidism can be made at the present time is a demonstration of a disturbance in calcium and phosphorus metabolism, (hypercalcemia and hypophosphatemia).

Now, as regards to the treatment of parathyroid tumors, I wish to state that there is only one accepted treatment and that is removal. No treatment with diet, no treatment with calcium, no treatment with hormones or with X-rays or any other known treatment is of any lasting benefit. Surgical treatment, however, should not be undertaken lightly, as it is not always as simple as one might expect. One reason for this is, as Dr. Hayes has pointed out in his case, that parathyroids vary. They vary in their size, from that of a green pea to a plum, they vary in number (normally there are four), they vary in their color, having been found of a pinkish hue, of a yellowish color as that of fat, to a dark color as that of liver, or the color of the thyroid itself, and they also vary in their location. Usually they may be found on the posterial and lateral aspects of the thyroid gland outside the capsule of this gland. They may, however, be found and frequently are, near and about the branches of the inferior thyroid arteries, and also about the superior arteries and their branches, or they may be found in the sulcus between the esophagus and the trachea, or found up as high as the pharynx, or as low as under the clavicle, or found deep in the anterior or posterior mediastinal spaces, which means that one must split or remove the manubrium in order to locate and remove them and besides they may be found within and part of the thyroid gland itself. With such variations in color and appearance, in size and location, plus the fact that one may mistake an aberrant or an accessory thyroid, a piece of thymus, or a hemolymph gland for a parathyroid one, it is essential that a competent pathologist be present at the operating table, in every operation undertaken for this condition, in order that a frozen section of a portion of the removed tissue may be immediately examined and accurately diagnosed.

To emphasize all of what I have said, and to present it in a much clearer manner than I could hope to express, I will conclude by reading you the summary of an article by E. D. Churchill and Oliver Cope, taken from a paper read by them at the last International Congress of Surgery, reporting their results in thirty cases of parathyroid disease, and published by them in the *Annals of Surgery,* 1936:

1. The corner stone of successful surgery of the parathyroids is a positive diagnosis.
2. An "exploratory operation" to confirm or disprove a doubtful diagnosis has little or no place in this field.
3. The findings of the laboratory are more exact than the dissection of the surgeon, and there is no point in the operation at which the operator may lay down his scalpel and find comfort in having disproved the diagnosis. Even the demonstration of four normal parathyroid bodies is not adequate because there remains the possibility that a small adenoma of a fifth gland lies tucked away in some inaccessible region of the mediastinum. A positive diagnosis is therefore a challenge to the skill and patience of the surgeon and when these have been exhausted in a fruitless search for an adenoma, the operator is privileged to say "the tumor cannot be found," but not "the tumor does not exist."

As to tumors of the parathyroid, I am sure you are familiar with the fact that adenomas are the most frequent type, cysts much less frequent and carcinomas rare.

Dr. R. C. Webb: A parathyroid tumor so closely resembles a thyroid adenoma that one should not apologize for not recognizing a parathyroid tumor. The case of hyperparathyroidism which I operated upon in January, 1934, and later presented before this society, I had scheduled for operation as hyperparathyroidism and there were several surgeons present, all of whom were experienced in thyroid surgery. When the tumor was exposed we were unable to assure ourselves that it was the source of the patient's disease until we saw the microscopic section. I am sure that Dr. Hayes should not feel apologetic for not recognizing the tumor in his case of suspected hyperparathyroidism. In my case the tumor was palpable preoperatively. Although the tumors are frequently located within the thyroid gland, they are usually situated outside the thyroid gland and are frequently palpable.

For several years it has been known that parathyroid tumors may be found within the thyroid gland. When Dr. F. H. Lahey discussed my paper at the 1934 meeting of the Western Surgical Association he called attention to eight cases in his own experience in which the parathyroid adenoma was discovered within the thyroid itself. (Minnesota Medicine, October 1935, page 669.)

The first case of hyperparathyroidism reported in 1926 by Mandl has reappeared in the literature due to a recurrence eight years later. I still have my patient under observation, and there is at this time no evidence of recurrence. She is of healthy appearance and has none of the symptoms of hyperparathyroidism. She does have a nephritis which may have no relation to the parathyroid disturbance.

Dr. J. M. Hayes: In answer to Dr. Webb, I will repeat that the patient had typical symptoms of hyperthyroidism and it was only accidentally that the parathyroid tumor, if it was such, was removed.

I have presented this with the hope that sometime

we might make a diagnosis of parathyroid tumor before the patient sustains a pathological fracture and the x ray must be brought in to make a diagnosis for us.

BENIGN TUMOR OF THE STOMACH

MARTIN NORDLAND, M.D.

THIS case is presented because of its rare surgical incidence. According to Hunt, the incidence of benign tumors of the stomach depends on whether the material is determined from autopsy or surgically. Surgical incidence is about .5 per cent to 5 per cent.

Of the latter group, those arising from the muscular structures are the most frequent and account for 60 per cent of all benign tumors of the stomach. Thirty per cent of this class of tumors have an epithelial origin. In a series of Judd and Hoerner, including 50 cases, 72 per cent were of muscular origin.

Most benign tumors of the stomach are symptomless and when symptoms occur, they are bizarre. There may be bleeding, massive or otherwise, with tarry stools and anemia and intermittent pyloric obstructions.

There are no clinical characteristics of benign tumors of the stomach. Usually they are not palpable. They

Fig. 1. Specimen of fibroma resected from the stomach wall.

Fig. 2. High power microphotographs of benign fibroma of the stomach.

In autopsy material, about 5 years ago, in the Department of Pathology, University of Minnesota, Rigler and Erickson, in investigating the records of 6,742 autopsies, found 187 gastric neoplasms of which 138 were malignant and 47 benign, an incidence of benign tumors of 26 per cent of all gastric neoplasms. Therefore, while benign tumors of the stomach are not uncommon, those that cause clinical manifestations are infrequent.

Hunt has further classified the origin of benign tumors of the stomach from three sources:

1. The epithelium.
   (a) Papilloma.
   (b) Adenoma.
2. Those from the connected tissues and vascular structures.
   (a) Lipoma.
   (b) Fibroma.
   (c) Myxoma.
   (d) Angioma.
3. Those from the muscular structures.
   (a) Myomas.
   (b) Neuromas.

can be confused with gastroduodenal disease because of anemia, bleeding and gastric motility. They are usually recognized by x-ray.

1. The filling defect is usually central rather than marginal.
2. The outline of the gastric shadow is usually preserved.
3. Spasm as in ulcer and cancer is absent.
4. Peristalsis is uninterrupted.

Case Report

The patient was a married woman, fifty-eight years of age, who presented herself with a typical history of recurrent cholecystitis and cholelithiasis. She had had several spells of gallstone colic over a period of four years with intervals varying from two weeks to six months. She complained that most of this time she had had varying degrees of indigestion. The last attack occurred about three weeks before admission to the hospital. X-ray study of the gallbladder revealed a non-functioning gallbladder but no evidence of stones. Because of the typical history of gallbladder trouble no preoperative x-ray examination of the stomach was made. There was nothing important in the history concerning the patient's past illnesses.

The patient was operated upon on March 26, 1936. The abdomen was opened through a high right rectus

incision and exploration of the abdominal contents revealed a thin walled gallbladder which emptied rapidly. The organ was apparently normal. On examination of the stomach a mass the size of a walnut was revealed on the anterior wall near the pylorus and close to the greater curvature. The mass was firm and seemed to be in the wall of the stomach proper. The pylorus was partially obliterated. The appendix was relatively normal with a few adhesions to the cecum near the base of the appendix. The mass described was excised and a pyloroplasty was performed. The wound was closed in three layers of sutures using interrupted linen sutures in the serosa. This procedure was followed by a typical appendectomy and the abdomen was closed in the usual manner.

The laboratory report by Dr. M. I. Smith, Pathologist, Northwestern Hospital: Specimen is an encapsulated tumor from the wall of the pylorus, 2.5x2 cm.; it is slightly yellowish and moderately soft. Microscopic sections show a leiomyoma with some chronic inflammation. The center is rather cellular.

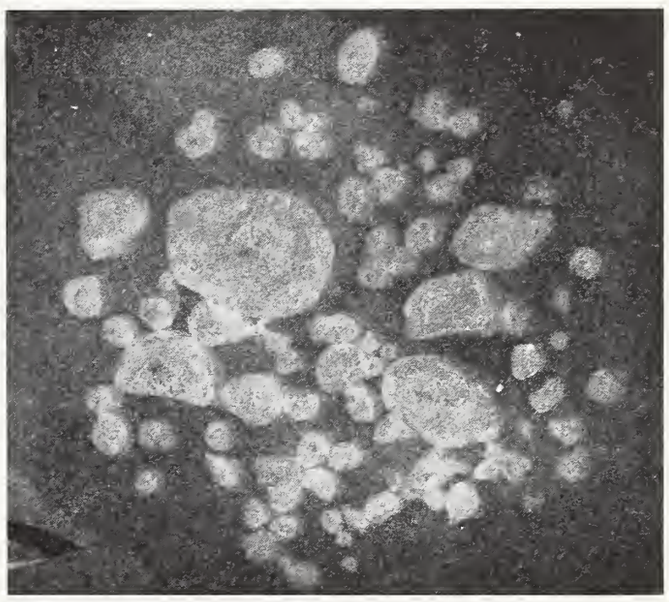
The patient made an uneventful recovery. She was seen on two occasions since the operation and, as far as I know, she is well at the present time.

Dr. Hunt, in a discussion of benign tumors of the stomach at the meeting of the Western Surgical Association at Kansas City in 1936, concluded that most of the cases are undiagnosed. He stated that 60 per cent of the tumors were removed by partial gastrectomy or pyloric resection. Because of difficulty of differentiating a benign from a malignant tumor, and because of hemorrhage, all benign tumors should be operated upon.

Discussion

Dr. E. A. Regnier: As Dr. Nordland mentioned, these tumors are more frequently found coincident with other abdominal diseases. The reports from the radiologists show a more frequent occurrence than would be indicated from surgical reports because many of these tumors are found in routine gastrointestinal studies. Likewise, autopsy specimens reveal a great many small leiomyomata that are of no clinical significance. If these small tumors, as well as polypae of the stomach, are included, the number of these tumors becomes increasingly high.

In a series of cases reported by Judd and Hoerner, 65 per cent of these tumors occurred in the prepyloric area in the stomach and 30 per cent in the mid-gastric region. The importance of these tumors lies in the fact that they may cause very severe symptoms. the chief of which is hemorrhage, and that they may degenerate into malignant growths. It is significant that in Judd's cases 46 per cent of these benign tumors were associated with peptic ulcer. In three cases the tumors consisted of pancreatic tissue.



The x-ray which you see before you shows a tumor in the pre-pyloric region which was diagnosed carcinoma by one of our radiologists. This man, sixty years old, complained of gastric distress for eighteen months. He had moderate secondary anemia with total achlorhydria. There had been a loss of weight of ten pounds in the last six months with gradual failing appetite. The physical findings were essentially negative. With the above history and the diagnosis of carcinoma of the stomach this man was explored. A tumor, 2 cm. in diameter, was found just above the pylorus. The tumor was excised and on the mucosal side there was a small crater ulcer. The pathologist reported it as a benign ulcer with a small tumor mass of pancreatic tissue above it. A pyloroplasty was done. The man made an uneventful recovery and is well today.

These benign tumors lend themselves to surgical removal by conservative surgery such as resection of the tumor with pyloroplasty or by sleeve resection or some other form of partial gastric resection. Their early removal should be encouraged because of the incidence of malignancy associated with them.

PROSTATITIS WITH CALCULI

T. H. Sweetser, M.D.

THE patient, a male veteran of the World War, forty-two years old, came to the hospital with complete retention of urine of twenty-four hours duration and with high fever and chills. He previously had had several attacks of complete retention and at other times had voided freely. He had been wounded during the war and also had contracted gonorrhea and syphilis at that time.

Rectal examination demonstrated a hard prostate containing stones which crepitated. The leukocyte count was 19,600, but the blood urea nitrogen was normal, the Wassermann was four plus, the urine contained some albumin, much pus, and a few erythrocytes. I had considerable difficulty passing the catheter even after passing bougies, but the intern had earlier passed a catheter without any difficulty. X-ray showed calculi filling the prostate and the prostatic urethra. A catheter was tied in place and preliminary treatment of his urinary tract and his syphilis was instituted.

Perirenal cystotomy was planned but finally a suprapubic cystotomy was performed instead. There was almost no trebeculation or thickening of the bladder wall. The bladder outlet admitted the finger. The prostatic urethra contained some small stones. The prostate, itself, was almost completely replaced by numerous stones, two of them being fairly large, and the mass of stones extended quite far back under the bladder trigone. The bladder outlet was dilated with the finger and the stones were removed. The shelf of remaining tissue between the prostate and the bladder was trimmed away and the prostatic space

packed with gauze. The wound was closed, the bladder being drained with a Feyer tube.

The stones were smooth and of a brilliant bronze color. On splitting some of them open this bronze shell was translucent and on microscopic examination apparently consisted of compressed prostatic substance (desquamated and disintegrated epithelium?). Within this shell was an inner zone of dense stone inside of which was a softer material of various colors. Microscopically the fragments of prostatic tissue removed showed chronic prostatitis. At several points minute calculi were seen in acini or ducts from which the epithelial lining had disappeared.

The man made a good recovery and had no further prostatic or urinary trouble. About eight or nine months later he suffered an acute decompensation of his heart and died with evidence of luetic aortitis and probably aneurysm.

PROCEEDINGS—MINNESOTA ACADEMY OF MEDICINE

(Continued from page 66)

process, appear to be quite uniformly better in the conservatively treated group, in which only a short cutaneous incision is made when a subcutaneous abscess is demonstrable.

The gynecologist was the first surgical specialist in the field to recognize the great virtues of conservatism in the management of acute infections. When its values are more generally appreciated, our results in the management of acute infections will be better. Were it not that the patient with a sore throat must swallow saliva, if not food and drink, several hundred times a day; or that patients with empyema, lung abscess or peritonitis must inhale and exhale some 25,000 times a day—if means were available to circumvent such necessary motion—undoubtedly the results of treatment of such infections would be much better. In the extremities, however, we have with the employment of plaster casts a satisfactory means of reducing motion to a minimum. The role of the surgeon is such infections is to provide as absolute physical and physiologic rest as he possibly can; to elevate the extremity concerned, in order to reduce filtration in the damaged capillary bed and to diminish existing edema. Only when pus is present should incision be made. Until specific immunologic or pharmacologic means are available with which to deal with pyogenic infections, we must continue to use those agents which we have learned from our own experience affect the issue most favorably.

The meeting adjourned.

A. G. SCHULZE, M.D.
Secretary.

Learning without thought is labor lost,
Thought without learning is perilous.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

SURGICAL PATHOLOGY OF THE DISEASES OF THE NECK. Arthur E. Hertzler, M.D. Surgeon to the Agnes Hertzler Memorial Hospital, Halstead, Kansas; Professor of Surgery, University of Kansas. 237 pages. Illus. Cloth binding. Philadelphia: J. B. Lippincott Company, 1937.

PRIMARY CARCINOMA OF THE LUNG. By Edwin J. Simons, M.D. Pp. 263; 30 illus., 2 col. plates. $5.00. Chicago: Year Book Publishers, 1937.

The purpose of this book is to provide the general practitioner with a compendium of the existing knowledge of a most important subject, for the sake of stimulating earlier recognition of the disease and thereby offering the patient his one and only opportunity for relief and cure by early, radical operation. To do this the author has literally combed the literature on the subject and has consulted freely with those of acknowledged standing who have given specialized attention to the various phases of the subject, added to his own personal observations and well grounded experience. The result is an amazing product of well directed industry and a keen example of the most useful type of textbook extant: a practical, scientific monograph.

This book should be on the desk of every practicing physician in the English-speaking countries. It contains the meat of the subject and nothing more. It is an earnest, honest effort to furnish much needed information on a very serious problem in clinical medicine; one that is becoming increasingly menacing with its known widening incidence. The author has done his work under circumstances of unusual difficulty and deserves warm commendation for the way in which he has surmounted every handicap. We hope to see the book become widely known—and read.

G. C.

PHYSIOLOGY IN HEALTH AND DISEASE, ed. 2. Carl J. Wiggers, Professor of Physiology, Western Reserve University. 1122 pages. Illus. Price, $9.00. Philadelphia: Lea & Febiger, 1937.

A book on physiology that is authoritative, and at the same time written in an interesting style, is not common. Wiggers' "Physiology in Health and Disease" fulfills all the requirements of a handy reference book which one can consult when the question of the physiologic disturbance underlying any condition arises. It is a storehouse of physiological facts, and the reader is not led through a maze of controversial discussion that only makes for confusion. The reputation of the author lends great weight to statements made in the book. It should be on the book shelf of every practising physician.

RADIATION THERAPY OF TUMORS WITH A CONSIDERATION OF THE POSSIBLE ADVANTAGES OF SUPERVOLTAGE X-RAYS*

ROBERT S. STONE, M.D.

San Francisco, California

UNTIL recent years malignant new growths were considered to be purely surgical problems. The term "surgical problem" includes not only the technical procedure of removing a tumor, but also the care of the patient with the tumor. The surgeon is expected to see that the patient has the proper preoperative care and the management after operation that will restore him to the best possible health. Such a conception of the surgeon's duties was not always held. For a long period extending into the nineteenth century surgeons were simply technicians who did not dare to stay too long in one community. With the advent of antisepsis and asepsis, operations were made more safe and new operations were made possible. In this period surgeons were so engrossed in developing new technics that they had little time to consider the patients upon whom they were operating. Now the technic of surgical procedures is standardized to such a degree that surgeons have been able to turn their attention to the problem of the patient as a whole.

Radiologists are passing through the same evolution as did the surgeons, but a little more rapidly. It is about forty-two years since the x-ray was discovered. Those physicians who have specialized in the use of these x-rays have been, like the surgeons of the immediate past, so intensely interested in the technical problems involved that some have lost sight of the patient as a whole. Surgery could not have advanced to its present high state if surgeons had not realized that the patient was involved as well as that part of his anatomy containing a new growth. Now radiology, too, as a branch of medicine, has come to that stage of its development at which the radiologist must view the patient as a whole. He must be prepared to take temporary charge of that patient and to see that proper care is given before and after irradiation.

Due to the preoccupation of radiologists with their technical problems, many physicians and surgeons have developed the custom of sending their patients for a specified quantity of radiation to a tumor instead of referring them to a radiologist for his management and treatment. It should be evident that such a procedure is not for the good of the patient. A prime problem in radiation therapy is for the radiologist to take charge of the patient who is ill, rather than of a tumor that needs irradiation.

Once the diagnosis has been established and the necessity for irradiation therapy jointly decided, it is assumed too frequently by both doctors and laity that all that is needed is an x-ray apparatus and a technician to operate it. A knife never cured a patient of cancer but a surgeon with a knife has cured many. Similarly, an x-ray machine has never controlled a cancer, but a radiologist using an x-ray machine has controlled many. To such a radiologist each patient is a particular problem, and many factors have to be considered which require a thorough medical appreciation of the constitution of the patient

*From the Department of Surgery, Division of Roentgenology, University of California Medical School. This study of supervoltage x-rays has been aided by a grant from the Christine Breon Fund for medical research. Citizens' Aid Society Memorial Address presented before the annual meeting of the Minnesota State Medical Association, Saint Paul, Minnesota, May 3, 1937.

and the type, size and location of the tumor, as well as a thorough knowledge of the handling of the x-ray apparatus so as to produce the most effective radiation.

The size and number of the areas which are to be treated must be considered in the light of the extent of the tumor, and the condition of the patient. Cachectic and anemic patients are known to stand radiation therapy very poorly, and hence only small areas can be irradiated, or small doses administered. The tumors in such patients respond very poorly. Even patients in the best of health cannot stand irradiation of too extensive areas of the body. With such facts in mind the radiologist must decide how many fields, and of what size, are to be used in applying the radiations.

The total dose desired must be determined in the light of the type of the tumor, its size and location. Some tumors which respond most easily and are called radiosensitive are the least curable. These shrink rapidly with the application of rather mild doses, but may require prolonged treatment if a cure is to be achieved. Other tumors are curable but are very resistant and require extremely large total doses which must be given in such a manner that the patient's normal tissues can stand them.

A decision on the total amount of radiation to be given requires a consideration of the number of days to be consumed in giving it. The total number of roentgens—the unit of exposure of x-rays—means little unless the total elapsed time and the daily distribution are considered. Some tumors respond best to a relatively small total dose given in a few days, while others require a larger total dose given in three or more weeks. The division of the desired irradiation into multiple daily sittings is necessary to preserve the integrity of normal tissues while delivering to the tumor a number of roentgens sufficient to destroy it. This question of the protraction of the dose is one that is only beginning to be understood. Not alone has the total number of days, and the amount of radiation to be given on each day, to be considered, but also the rate at which the radiation is to be given during each sitting.

It is a popular conception that the powerful machines which can deliver large amounts of radiation in short periods of time are the most effective. This may or may not be true. There is some evidence to show that radiation delivered in small amounts per minute is more effective in many cases than the same total quantity delivered in large amounts per minute. If this is found to be true, the trend will be toward the use of less powerful apparatus for longer periods of time, rather than toward more and more powerful machines.

The distance of the x-ray tube from the patient must also be considered. If a large area is to be treated as a single field, this distance must be great in order to obtain a uniform irradiation of the whole surface. Short distances can be used when a small field is to be treated. This target skin distance also controls to a certain extent the amount of radiation that penetrates to the depths. The greater the distance, the greater is the dose at any given depth. Skin lesions can be treated at short distances but deep-seated lesions require long distances.

Last, but not least, come the problems of the filter and the voltage to be used. These two factors control the quality of the radiation. With regard to the filter, the only statement to be made at present is that increasing the filter, either in thickness or in the density of the material used, cuts down the number of soft x-rays which reach the patient. No amount of filter can give harder rays than the hardest produced by the particular voltage being used. It is common knowledge that soft (or long wave-length) x-rays are absorbed in the skin and the subcutaneous tissues, while a greater proportion of harder (short wave-length) x-rays penerate to the depths. Hence, the choice of filters is governed by the depth to which we wish the radiation to penetrate before being too greatly absorbed.

The problem of voltage is probably the most vexatious one at the present time. There is a common belief, held by both the medical profession and the laity, that higher and higher voltages are synonymous with better and better treatments, and more and more cures of cancer. This popular feeling is stampeding radiologists into procuring apparatus capable of producing higher and higher voltages. Let us carefully consider the facts which are known at the present time. At the University of California Hospital we have an apparatus which, since 1934, has run at supervoltages for treatment purposes. For the past year it has been operating continuously at

one million volts. In adjacent rooms we have machines capable of producing 200 and 100 kv. radiations and we have endeavored to compare the physical and clinical observations on the various voltages as accurately as possible.

Radiations act on cancer cells and the surrounding tissues by means of the ionization which they produce in them. Within the range of x-rays available, the amount of ionization depends on the quantity of radiation that reaches and is absorbed by the tissues which we desire to affect. The voltage used regulates the energy of the x-rays produced, and is therefore the determining factor, up to a certain point, as to the depth to which the rays will penetrate before being largely absorbed. It was long ago conceived, therefore, that if x-rays could be produced by higher and still higher voltages, they would penetrate farther and farther into the tissues before being absorbed. When the advance was made from 100 to 200 kv. radiations, it was found that the rays could and did penetrate farther, and that more marked effects were produced in the depths.

It must be kept in mind that the increase in the quantity of effective radiation at a given depth must be in greater proportion than the increase in that quantity on the surface if the radiation is to be of value. A method of expressing the amount of effective radiation at depths in percentages of the amount on the surface was devised. These percentage figures are called depth doses. We have compared the depth doses produced by 1,000 kv. radiations with those produced by 200 kv. radiations.

It was found soon that the 1,000 kv. radiations penetrate better than the 200 kv. radiations. There is very little difference in the depth doses at from 4 to 6 cm., but, as greater depths are reached, the difference between the two becomes great. Using a field 20 by 20 cm. we found the depth dose at 10 cm. to be 46 per cent for 200 kv. and 55 per cent for 1,000 kv. radiations. It would seem until we look further into the problem, that higher voltage is very much better.

Since it is necessary to administer 100 per cent or greater depth doses to most tumors, it is obvious that more than one field of entry for the radiation is necessary. If the depth dose at 10 cm. is 50 per cent, and it is desired to give a dose of 100 per cent at a depth of 10 cm., the irradiation would have to be applied through two surfaces, 100 per cent to each. The accumulation of the two 50 per cent doses would give 100 per cent at the center point. The two portals of entry of the radiations would probably have to be directly opposite to each other. Some of the x-rays pass through the body and affect the skin on the opposite side. This is called the "exit dose." This exit dose is much greater for 1,000 kv. than for 200 kv. radiations, because of their greater penetration. In calculating how much the skin will get, the exit dose must be added to that directly applied. Hence the amount applied directly must be reduced more for the 1,000 kv. than for the 200 kv. radiations if the skin dose is to be kept at a total of 100 per cent. The smaller amount directly applied reduces in proportion the amount reaching the depth, and we find that the depth dose at the center of a body treated from directly opposite sides is not nearly as much greater as would be expected on a superficial consideration of the subject. In fact, we found that when thin parts of the body, such as the neck, are treated, a greater "center" dose can be given with 200 kv. than with 1,000 kv. radiations. The actual amount of the depth dose depends on the size of the fields irradiated. We found that if fields 10 by 10 cm. were used in parts up to 12 cm. thick, doses could be given by 200 kv. radiation as large as, or even larger than, those supplied by 1,000 kv. With large fields such as may be used on an abdomen, 20 by 20 cm., a thickness of more than 18 cm. was reached before any improvement in the center dose could be found with the higher voltage. Hence, from the aspect of physical measurement, it would appear that 1,000 kv. radiations are of increased value only when the parts to be radiated are thick, or the fields to be used are small, or direct cross-fire can be avoided.

Clinically, other facts are found. It is a very common belief that the effect on the skin is the sole factor limiting the amount of radiation which a patient can receive. This is not true. While treating lesions of the abdomen or pelvis it has been found frequently that the effect on the bowel, *i.e.*, the erythema produced in the mucous membrane, is the limiting factor. When we have used 200 kv. heavily filtered radiations, applied from a distance of 80 cm., the intestinal reaction has frequently become so severe that treatments had to be interrupted or altered be-

fore the skin had received its maximum dose. The effect on the lungs when treating over the chest, and the effect on the mucous membrane of the throat when treating over the neck are known to limit treatments in those regions. It would seem that with 200 kv. radiations we are able to get as great a dose into the depths of the body as can be tolerated by the normal tissue in many cases. One thousand kv. radiations can do no better than this. Some other method of differentially affecting the tumor more than the normal tissue around it must be found.

Without further discussing the points involved, our general conclusions may be stated. First, supervoltage delivers greater depth doses from a single field, the differences being more marked the smaller the field and the greater the depth considered. Secondly, with supervoltage radiations there is less scattering into the adjacent tissues. Thirdly, the amount of x-ray in a supervoltage beam does not fall off so markedly on the edge as it passes through the body. This results in a more uniform dose to all points at a given depth. Fourthly, when using cross-fire technic, the large exit doses offset to some extent the practical value of the larger depth doses, the supervoltage being advantageous only if (a) direct cross fire can be avoided, (b) the part is thick, (c) multiple small fields can be used without excessive overlapping of the exit skin fields.

The 1,000 kv. apparatus has been in operation only since May, 1934. Five-year "cures" are therefore not yet in existence. We have, however, compiled some statistics for various lesions which show the unfortunate fact that, with the number of patients already dead, we cannot expect any great improvement in the five-year results when the necessary time has elapsed. It should be remembered that the same technic, except for voltage, has been used on the 200 and 1,000 kv. machines. Let us now consider what has been accomplished with specific lesions.

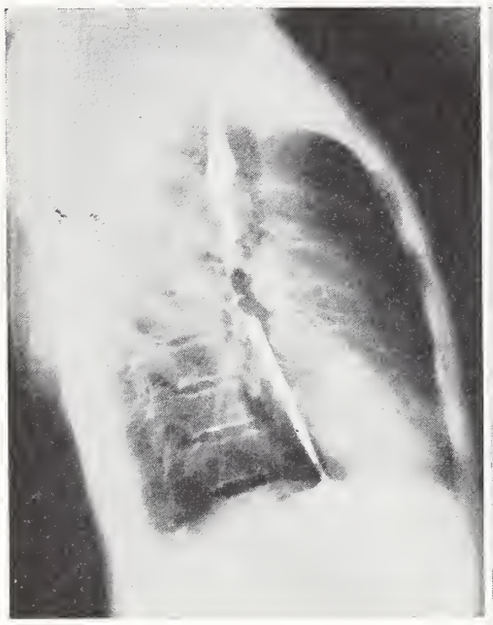

Fig. 1. Patient A. B. Cancer of the esophagus.

Fig. 2. Same patient as Figure 1, eight months after x-ray therapy to the cancer of the esophagus.

Cancer of the esophagus is recognized as a hopeless disease. Eight patients suffering from it have been treated, six are dead. Of the two alive, one has survived a year, and the other nine months, since the beginning of treatments. Both are comfortable at the present time.

Figure 1 shows the lesion in the middle third of the esophagus of patient A. B. as seen on July 6, 1936. Following this examination he was given 250 r per day to a total of 2,500 r per field to four fields in a period of 23 days. Figure 2 shows the same patient eight months later. Preceding the first examination a biopsy was taken by means of an esophagoscope. Following the second examination another esophagoscopy was performed and no evidence of the previous cancer could be found. The patient is at present enjoying very good health.

Figure 3 shows the biopsy specimen of a second patient, G. S., who had a similar lesion in a similar place. This patient received a prolonged course of therapy, following which his ability to swallow was improved. The treatment ended on January 22. On February 28 the patient died and an autopsy was obtained. Scarcely any evidence of the carcinoma of the esophagus could be found, but there were evidences of fibrosis of the lung. The patient also had pernicious anemia, generalized arteriosclerosis, mild diabetes and terminal bronchopneumonia. Figure 4 shows one of the few small islands of cancer cells which were demonstrated after making serial sections of the esophagus. It is easily seen that, whereas the cells in the specimen taken before treatment appear to be growing wildly and invading widely, those in the section made after irradiation appear to be adult in type with no evidence of growth and to be encapsulated. It is evident that in this case the x-rays had almost eradicated the tumor.

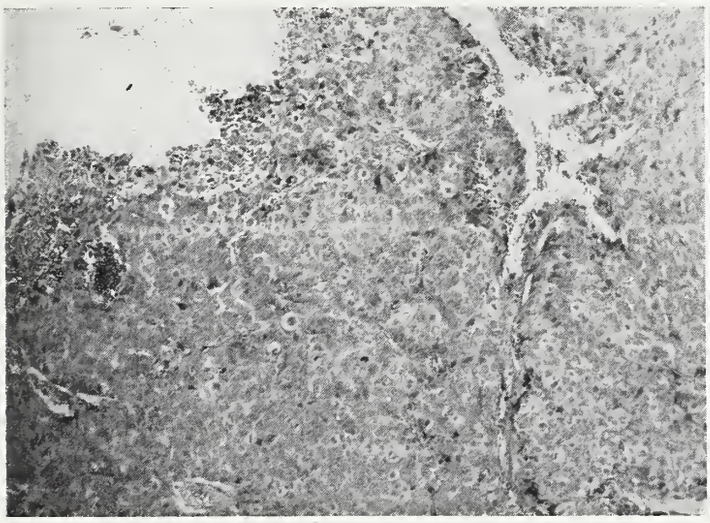

Fig. 3. Biopsy specimen of cancer of the esophagus. Patient G. S.

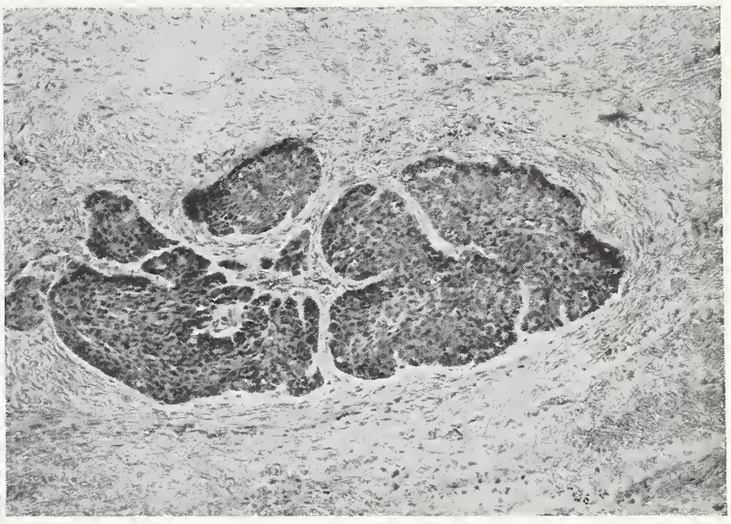

Fig. 4. Specimen from autopsy of patient G. S. showing encapsulated islands of cancer tissue one month after x-ray therapy.

In treating cancer of the uterus we have cooperated closely with the Department of Obstetrics and gynecology, headed by Dr. Frank Lynch. Most of the patients were given local radium treatments by members of that department, followed at once by external irradiation. Sixty patients have been so treated. Of these, twenty are dead, twenty-one are alive with some evidence of cancer, and nineteen are alive without evidence of cancer. During the immediately preceding period of two years and seven months, during which 200 kv. radiations were used, 63 patients were treated. At the end of that period, twenty-one were dead, eighteen alive with some evidence of cancer, and twenty-four alive with no evidence of cancer. In this series there were four patients with cancer in the first stage, while in the 1,000 kv. series there were none with the disease in that early stage. Even taking this fact into consideration, it is obvious that the 1,000 kv. radiations have produced no better results than the 200 kv. radiations.

Several of the uteri that had been irradiated thoroughly were removed by Dr. Lynch at varying intervals after the treatments. A very radical Wertheim procedure was performed. This was done in order to see what happened to the irradiated tumors and the surrounding tissues. He found that foci of tumor cells which appeared to be alive were found frequently and that the surrounding tissues showed a considerable amount of unfavorable change. Such findings as these give us a new conception of what happens after irradiation. In deciding on a practical course to follow in treating patients with cancer of the cervix, we must still rely on the fact, shown by so many authorities, that radiation produces as high a percentage of five year survivals as any other method, and a much lower mortality than surgery. The patient is interested in living as long as possible, even if she has a few foci of cancer cells encapsulated in the pelvis.

The patients having cancer of the breast have had such varied combinations of treatment that little can be concluded from our statistics. All of the patients with early cancers were operated on, and either received no radiation or only a

TABLE I. PATIENTS TREATED WITH 1,000 KV. RADIATIONS DURING TWO YEARS AND SEVEN MONTHS

postoperative course. Thirty-seven patients in all were treated. Of these, seventeen are dead, twelve are alive with evidence of the disease, and eight are alive with no evidence of cancer. Of these eight, seven received only post-operative irradiation and were probably cured of cancer by the surgery. Ten patients were treated by x-ray alone. They had either extensive axillary metastases or some complicating disease. Six are alive and comfortable, but still have evidence of cancer. Three are dead. Only one is alive with no evidence of malignancy.

An examination of some breasts removed solely for study after thorough irradiation showed that most of them had some cancer tissue persisting, but always altered considerably by the treatments. This finding is the same as reported above for esophageal and uterine carcinomata.

The problem of deciding the most practical method of treating cancer of the breast is solved by analyzing the statistics of the results of surgical treatment. In our clinic, Dr. E. I. Bartlett did this some years ago and found that the only patients with a high percentage of cures by surgery alone were those with a small movable tumor in the outer half of the breast and no palpable axillary metastases. In all other cases the percentage of cures was so low that other methods of treatment should be tried. As a result of this I recommend that all patients except those with lesions of the type noted above be given a thorough course of radiation, followed by a radical operation if there is no spread beyond the axilla, and if it seems practically possible to remove all the axillary lymph nodes after the reaction to irradiation has subsided.

Space does not permit a discussion of all types of cancer treated, nor would it be profitable. Table I shows the statistics for many of the cases treated between May, 1934, and December, 1936, by 1,000 kv. radiations. These patients were not all treated by irradiation alone. From the table we can gather the significant and disappointing fact that there are so many patients already dead that few will be living at the end of five years.

I have not tried to deal with the results of radiation therapy as a whole, but I have tried to show that very little improvement in results is to be expected from 1,000 kv. radiations. It would not be doing justice to radiation therapy to conclude this discussion on such a pessimistic note. Every physician knows of some patients who have been cured by this means. They are the ones who have presented themselves with very localized cancers. The statistics and the microscopic evidence of persisting cancer in treated patients do not tell the complete story. A great many patients who come in suffering severely from cancer can be relieved of a large part of their suffering. Their tumors can be reduced in size, and an attitude of depression changed to one of hope. The older textbooks are filled with pictures of emaciated, suffering patients in advanced stages of cancer. By our radiation methods we are able to keep many such patients comfortable until they die of internal metastases, such as those to the liver, and their deaths are much less painful.

Summary

1. The status of the radiation therapist is considered and it is shown that, if he is to be of the greatest value to those suffering from cancer, he must take his place beside the surgical therapist as a well-rounded physician. He can no longer remain a "technician," interested only in administering a dose of x-ray to a tumor, without concerning himself with the patient who has the tumor.

2. The method of giving x-ray therapy has

not yet become standardized. There are many factors to be considered. Each patient is a new problem, and a great deal more depends on the clinical judgment and technical knowledge of the physician administering the x-ray therapy than on the particular apparatus he uses.

3. Many factors have to be considered before giving x-ray therapy:

(a) The size of the area to be irradiated depends on the extent of the primary tumor and its spread; and on the condition of the patient.

(b) The total dose to be applied depends on the type, size and location of the tumor. The number of days required for giving the treatment, and the rate at which the x-ray is applied at each sitting are of great importance.

(c) The voltage to be used is the most pressing question at the present time. The popular conception that higher voltage means better treatment is not generally true. More powerful machines are not necessarily more useful. A comparison is made between the physical measurements obtained by using 200 kilovolt and 1,000 kilovolt apparatuses. For thicknesses corresponding to many parts of the body, as large a dose can be given to internal parts by 200 kilovolt radiations as by 1,000 kilovolt radiations. Clinically it is unnecessary to go above 200 kilovolts in order to get as large a depth dose as can be tolerated. Advances in x-ray therapy are as likely to result from a better use of the apparatus we now have as from new kinds of apparatus.

4. Various specific tumors are discussed as to the method of treatment and the effect of the supervoltage x-rays on them. The number of patients who have died in the two and a half year period during which the million volt therapy machine has been in use indicates clearly that no very appreciable advance has been made by increasing the voltage.

5. The number dead or the number cured does not tell the whole story. Many of the patients treated were made much more comfortable and their remaining years of life more enjoyable.

THE ENERGY METABOLISM OF THE HEART IN FAILURE*

MAURICE B. VISSCHER, Ph.D., M.D.
Professor of Physiology, University of Minnesota
Minneapolis, Minnesota

THE failing heart is, in general terms, one that is unable to pump sufficient blood to meet the needs of the body. From the point of view of etiology there are many kinds of heart failure, but to focus attention on a single phase of the problem, only myocardial failure will be considered, without reference to the complicating factors of disturbances of rhythm and conduction, and disturbances in coronary blood flow. It is not implied that the principles to be discussed do not apply in the presence of complications due to the aforementioned factors, but the case is simpler when these conditions are excluded.

In the experimental animal, one can study either acute or chronic failure by experiments. To simulate most closely the more common types of failure it would be desirable to do experiments of the chronic type. Unfortunately, methods for study of the more important factors in long-time experiments are not available and therefore experiments have had to be limited, for the most part, to acute situations. Reasons will be advanced for believing that the results so obtained may be applied to the solution of the clinical problem.

A reduction in the ability of any machine to do work might conceivably be due to either one of two factors. Either the amount of energy available may be diminished or the ability of the machine to convert available energy into work may be impaired. Without experimenta-

The work on digitalis glucosides reported in this paper was subsidized partly by funds from the Graduate School of the University of Minnesota and by a grant from the Sandoz Company.

tion it would be impossible to decide which of these two mechanisms were responsible for the failure of the heart to do its work when it deteriorates.

There are several chemical processes involved in the liberation of energy in muscle contraction. According to the best evidence available at the present time, contraction is associated with a breakdown and subsequent resynthesis of creatine phosphate and adenyl-pyrophosphate, and with the formation of lactic acid from glycogen through several intermediate steps. In the ultimate recovery from contraction there is an oxidation of carbohydrate and fat, liberating energy for the restoration of the system. The stores of creatine phosphate and glycogen might possibly be depleted in the failing heart and thus there might be a lack of the materials which provide the immediate source of energy for the contractile process.

Experiments conducted in collaboration with Mulder[14] showed that so long as the heart was supplied with adequate oxygen there was no significant decrease in glycogen stores. Therefore, it seems very unlikely that failure should be due to the lack of carbohydrate in the heart.

The question of a possible lack of creatine compounds in the failing heart has been attacked from several angles and the results indicate, as will be seen below, that this factor is probably not the critical one in most types of failure. Several investigators have measured the creatine content of hearts in relation to failure. Seecof, Linegar, and Myers[10] made the first extensive investigation. Hermann, Decherd and Oliver[5] studied the creatine content of human heart muscle in 105 cases. They found a 30 per cent decrease in creatine in the congestive failure cases as compared with the normal. Bodansky and Pilcher[1] studied the creatine content of the human heart at autopsy in 310 cases. The hearts from patients dying from congestive heart failure showed somewhat less creatine than did the hearts of normal individuals. There were some failing hearts, however, wich had a creatine content well within the normal range and the average depletion was only a little more than 20 per cent. In view of the finding of high creatine values in some of the congestive failure cases and particularly in view of the fact that terminal anoxemia is apt to be present longer in patients dying of congestive failure than from other diseases, particularly than in the case of accidental death, it seems that these results must be taken to indicate that the decrease in heart muscle creatine is not the main causative factor in this type of failure. The work of Hermann and Decherd[4] would seem to indicate quite clearly that when the blood flow, and consequently the oxygen supply to tissues are interfered with as in the case of infarction, the creatine content of heart muscle does drop abruptly. The changes that occur in infarction, however, have no particular bearing upon our present problem. Furthermore, there is no significant accumulation of creatine in the blood of the heart-lung preparation when the heart fails. Previously unpublished experiments show that the creatine content of the blood in the heart-lung preparation varies between 3.4 and 7.3 mg. per cent. In two out of five experiments there was an increase of 0.5 mg. per cent in three hours of progressive failure and in three experiments there was no change. If creatine phosphate were to have been lost from the heart it might have been expected that one would find an increase in creatine in the blood. Since this did not occur it may be inferred that there was no loss of creatine phosphate from the muscle during these periods.

Further evidence concerning the availability of energy in the failing heart is to be found in observations on the total oxygen consumption. When recovery from contraction is occurring in a normal way the oxygen consumption of muscle is an index of its total energy expenditure. This is true because the muscle is restored to its resting state by oxidation processes, and in the last analysis all the energy of contraction must come from the oxidation of either carbohydrate or fat. Thus a determination of oxygen consumption should provide a means of measuring the total energy output of the heart in contraction under various circumstances. The only requirement that must be satisfied in order that this may be a valid procedure is that the heart be adequately supplied with oxygen. This can be accomplished readily in the heart-lung preparation, which has been used for studies on this question.

As an introduction to what will be said concerning the metabolism of the heart in failure,

certain general principles regarding the dynamics of heart muscle should be reviewed. First one should consider the normal mechanisms of response of the heart to changes in its load. Starling[11] formulated as the Law of the Heart,

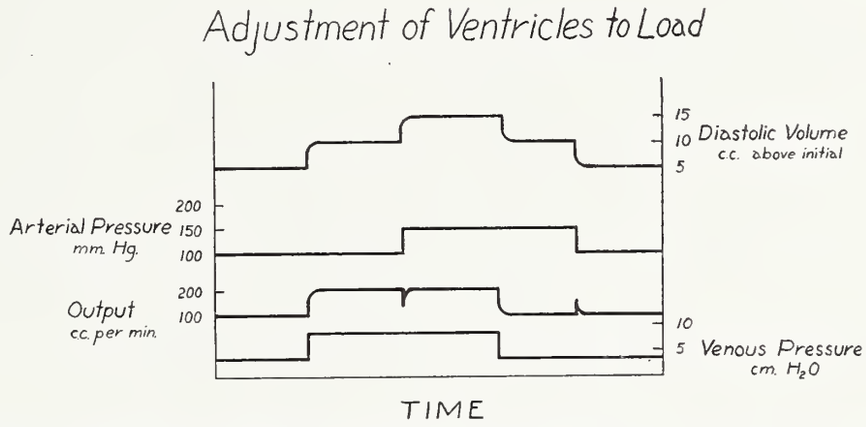

Fig. 1. Schematic, composite diagram showing mechanism of adjustment of mammalian heart to increases and decreases in load.

the rule that in order to do increased work the ventricles of the heart must dilate. In Figure 1 is presented a composite and somewhat schematic diagram of the results of many experiments on this question. When the work that the heart is made to do is increased by raising the venous pressure, thus increasing the filling, the diastolic volume of the ventricles rises. Again, when the arterial resistance is increased, producing a hypertension, the heart is able, after a few beats to eject the same amount of blood as before, but from a greater diastolic volume. When the inverse changes in filling pressure and arterial resistance are made, the diastolic ventricular volume diminishes. In every case, unless the heart is failing, or excessive loads are imposed, the heart arrives shortly at a constant diastolic volume, which it maintains until a change is made in the filling, or in the peripheral resistance. The general rule may be derived from such observations that when the heart is called upon to do increased work of any type, it adjusts itself by virtue of the fact that the residual blood increases to the requisite quantities so that the diastolic volume will be great enough to permit the heart to eject a quantity of blood equal to that delivered to it during each cardiac cycle. Or, stated more simply, if somewhat less completely, the heart responds to the imposition of more work by diastolic dilatation. The process, moreover, is reversible.

The ability of the heart to do larger amounts of work at greater diastolic volume results from the fact that the amount of energy liberated in contraction is dependent upon the diastolic volume or fiber length.[12] Regardless of whether the increase in diastolic fiber length is brought about by increased arterial pressure or increased filling, the oxygen consumption or total energy liberation is the same at any diastolic volume. It becomes apparent that the diastolic volume law is valid because energy liberation depends upon diastolic volume. The heart is able to do more work when it dilates under increased pressure or increased filling because at the greater diastolic fiber length more energy is liberated.

It has long been known that the amount of work the isolated heart is able to do, contracting from a particular diastolic volume, diminishes with time. This phenomenon has been referred to as spontaneous failure in the isolated heart. At least superficially, and it is believed fundamentally as well, this phenomenon is not dissimilar to failure in the clinical sense, which is also associated with cardiac dilatation. In clinical heart failure the heart dilates even though it is called upon to do a minimal amount of work. Transferring the results from the heart-lung preparation to the case of the human heart, we would say further that in failure the heart dilates in order to do a constant minimal amount of work. From the point of view of the pathologic physiology of the heart this point is of prime importance. Dilatation is a mechanism of adaptation and is not in itself an unfavorable, but rather a desirable reaction. It is only the underlying conditions which make

dilatation necessary which are unfortunate. The ability of the heart to dilate in failure is actually a life saving compensatory mechanism.

The important question arises as to whether the necessity for dilatation in failure in order to carry a constant load is occasioned by a decrease in the total energy liberation or by a decline in the efficiency of utilization of energy by the contracting muscle. This problem has been attacked experimentally in the mammalian and the amphibian heart. In the simplest case, that is, in the single ventricle of the turtle, the work performed, and the oxygen consumption were measured[8] and it was found that the latter was constant when the diastolic ventricular volume was held constant over three hours of beating, but the work that could be done fell off markedly. This finding means that the proportion of the total energy used which was put to useful work decreased. In other words the efficiency of the ventricle as a machine decreased as the heart muscle failed. The efficiency which was originally 17.5 per cent or thereabouts in most fresh hearts, fell to as low as 5 per cent in three hours.

In the mammalian heart this general principle has been confirmed.[7] The heart-lung preparation removed from the dog's body and placed in a closed chamber immersed in a constant temperature bath was employed. The ventricular volume was measured by placing the heart in a cardiometer, the work was controlled by altering the venous inflow, and the energy expenditure was calculated from the oxygen consumption. It was found that except when massive edema of the heart or lungs occurred, the diastolic volume law was valid even when the heart failed badly. It is possible to induce or accelerate failure in the heart-lung preparation by the administration of histamine or by adding anesthetics to the blood. It was found that histamine tended to diminish the energy output at constant external diastolic volume but it could not be definitely ascertained whether the histamine effect in this regard might not have been due to the massive edema which it produces. Anesthetics such as amytal and alcohol decreased the work that the heart was able to do without correspondingly influencing the total energy liberation. In other words their effect was specifically upon the efficiency of the heart muscle. In spontaneous and induced failure, therefore, the heart is seen to be a less efficient machine than it is when normal. The energy that can be put into contraction is as great as before, but a smaller fraction of it is usefully employed.

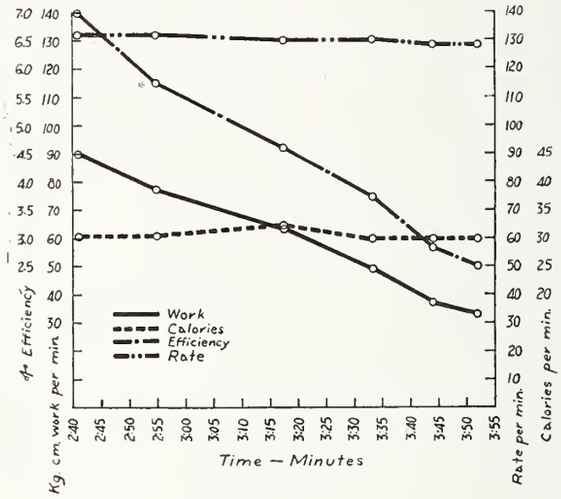

Fig. 2. Spontaneous failure in the heart-lung preparation (dog). The external work expressed in kg. cm. per minute, the total energy liberation measured by oxygen consumption and expressed in calories per minute, the efficiency calculated from these two quantities and the heart rate plotted against time.

In Figure II are presented the results of an experiment performed in the present study, illustrating the decreased efficiency which occurs in spontaneous failure in the heart-lung preparation when the diastolic volume of the ventricles is maintained constant over the course of an hour. It will be noted that the work which the heart could do at constant diastolic volume diminished so greatly over this period of time that the efficiency of the heart declined about 60 per cent.

In all, more than 100 experiments have been performed in which spontaneous failure has been observed and in none of the cases, unless massive edema has developed, has there been any significant deviation from the findings presented above as typical.

Various factors alter the rate at which failure occurs in the heart-lung preparation. It was found[15] that the addition of a small amount of insulin would improve the condition of the heart when it is first added to the perfusion fluid. After the first injection of insulin in a given preparation, subsequent injections have no further effect. Furthermore, the improvement is only temporary and progressive failure super-

venes after a short time. Likewise the addition of glucose to the circulating blood improves the condition of the heart muscle with respect to its efficiency. In spite of high blood sugar levels, however, the heart eventually fails as it does when the blood sugar is allowed to fall. These factors, although important, do not prevent myocardial failure for any length of time. Increasing the calcium content of the blood was found to increase both the energy liberation and the efficiency of the dog's heart.[8]

The only agents so far investigated capable of permanently increasing the work and the efficiency of the heart in the preparations we have employed are the glucosides of the digitalis series. This fact seems to be not without importance in understanding the physiological mechanisms by which the digitalis glucosides act. There has been great confusion in the literature regarding the mechanism of the therapeutic action of digitalis. The monographs of Cushny[2] and Luten[6] may be consulted in connection with the history of the subject. It is sufficient for our purposes to say that there has been no clear evidence of a therapeutically useful effect of digitalis upon the heart muscle itself, until recently. The most obvious effects of digitalis upon the heart of experimental animals are upon excitation and conduction. The occurrence of increased tonus, so-called, in the ventricle has long been known, but there is no necessary relationship between increased tonus and increased work capacity. Several investigators have performed inconclusive experiments on the effect of digitalis glucosides in the heart-lung preparation, failing in general to control the diastolic ventricular volume, and no consistent results were obtained until the problem of the work capacity of the failing heart was investigated at constant diastolic fiber length.[7] It was found that strophanthin, scillaren-B, ouabain and the digilanids of Stoll[13] all had a beneficial effect on cardiac efficiency, producing an increase of as much as 200 per cent in this factor.

A further study has been made of the action of the three components of the digilanids in digitalis lanata. These purified, crystalline, natural glucosides have been studied separately.* As might have been anticipated their activities are quite different. Digilanid C is from five to ten times as potent in producing an increase in efficiency as is digilanid A. An example is given in Figure 3 of an experiment in which 2 mg. of digilanid A was administered after

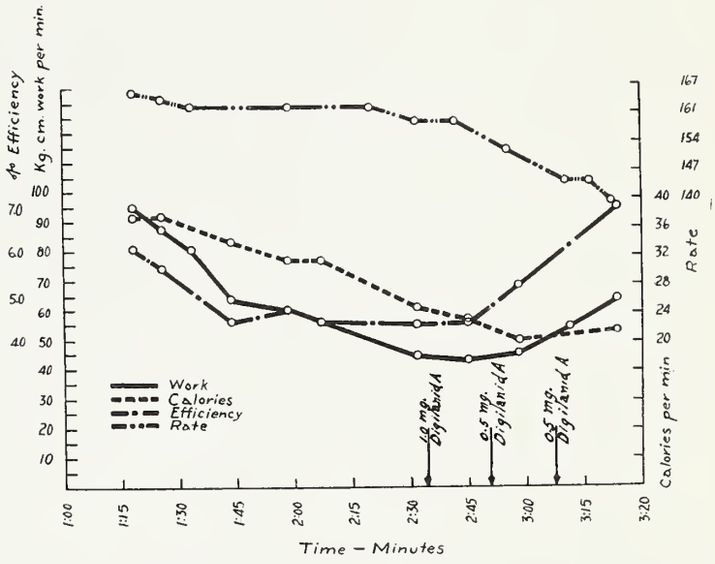

Fig. 3. The effect of 2.0 mg. digilanid A on energy liberation, work, efficiency, and heart rate in the heart-lung preparation.

a period of failure and the resulting change in efficiency was from 4.5 to 7.0 per cent. In a comparable experiment, Figure 4, O.2 mg. of digilanid C increased the efficiency from 5.3 to 10.0 per cent. The effects of digilanid C come on somewhat more rapidly than do those of digilanid A. This seems not to be due to differential solubility, because the C is less soluble that the A. Rothlin[9] has reported that by the ordinary cat assay method, digilanid C is only slightly more active than digilanid A. By the frog's heart method digilanids A and D have identical activity according to Rothlin. These methods really measure the toxicity of digitalis bodies, giving the dose necessary to kill the animal or to stop the heart. It is quite evident that the toxic dose method does not give evidence concerning the efficiency-increasing power of digitalis glucosides. The classical methods of assay may give useful information in indicating the fatal dose of a glucoside preparation but since equally toxic substances may have ten-fold differences in their therapeutic actions it is obvious that one should not expect such methods of assay to give reliable information as to the more important actions of the drugs, assuming for the purpose of this argument that the increase in the ability to do work is the thera-

*I am indebted to the Sandoz company for a supply of the separate digilanids A, B, and C.

peutically desirable action of digitalis. Only two experiments have been performed up to this time on digilanid B and it is therefore impossible to make any statement as to its actions

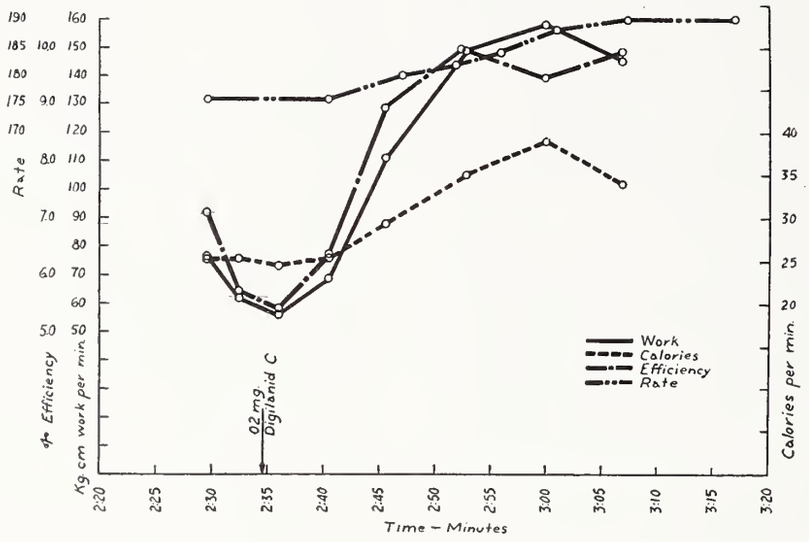

Fig. 4. The effect of 0.2 mg. digilanid C on energy liberation, work, efficiency, and heart rate in the heart-lung preparation.

other than to say that it is very much less active than the digilanid C.

In connection with other reputed cardiac tonics, the action of coramine should be mentioned. The effect of this widely used drug upon cardiac efficiency was studied[7] and it was found that its action upon the heart muscle was deleterious, in the sense that it resulted in a decreased efficiency. It would, of course, be inappropriate to condemn this drug generally because it has one undesirable action, inasmuch as it might be useful in producing a peripheral vaso-constriction or in stimulating respiration, in spite of an unfavorable direct action on cardiac muscle. However, there are many circumstances which might arise in which such a drug as coramine might be employed, and in which the efficiency of the heart muscle might be the critical factor in determining the life or death of a patient. Under such circumstances the employment of an agent which decreases the amount of work the heart can do with a given expenditure of energy is definitely contraindicated.

Finally, the justifiability of the use of the acutely failing heart-lung preparation in such studies as these should be considered. It must be recognized that one is unable to prove that the situation in the dog's heart is comparable to that in the chronic failing human heart. There is, however, much collateral evidence to support the view that the principles involved are the same in the two cases. In both instances the heart has to dilate in order to do the same amount of work. In both, a decrease in the load results in a decrease in diastolic volume. Moreover, in both, the therapeutically useful digitalis glucosides result in a decrease in ventricular volume. There is no evident discrepancy between the situation in the two cases. The burden of proof would therefore seem to be upon those who would deny the legitimacy of the transference of conclusions drawn from experiments on failure in the dog heart to the situation in uncomplicated myocardial failure in man. As noted above, disturbances in conduction, rhythm and coronary circulation complicate the situation, and also, it may be added, when hypertrophy is involved the problem is obviously less simple. It is beyond the scope of this paper to enter into a full discussion of these complications but it is the author's opinion that with certain minor reservations, the general principles described still hold.

Summary

1. The inability of the heart to maintain its work output in failure has been shown to be associated with a decrease of the mechanical efficiency of the heart muscle.

2. The efficiency of the failing heart can be increased temporarily by the administration of

glucose, insulin or calcium salts. It is profoundly improved by the administration of glucosides of the digitalis series. It is suggested that the major factor in the beneficial effect of digitalis in myocardial failure is the improvement in mechanical efficiency.

3. The several glucosides from digitalis are not equal in their potency in this regard nor is the effect on efficiency parallel with the toxic properties measured by the usual assay methods. There is as much as a ten-fold discrepancy between therapeutic efficiency and toxicity determination by the frog's heart and the cat method.

CONSERVATIVE RENAL SURGERY*

ROLAND G. SCHERER, M.D.

Bozeman, Montana

THE term, conservative renal surgery, has taken on a new meaning in recent years. Plastic operations on the renal pelvis and the ureter may become truly radical when they cause long illness, great renal damage or necessitate secondary nephrectomy. Küster made the prediction, many years ago, that plastic operations would become the accepted method of treatment for hydronephrosis. To the present time this prediction has not been fulfilled, and the multitude of surgical procedures used in its treatment serves to indicate in a large measure the lack of general success in the use of plastic renal surgery.

Küster was probably the first to reimplant the sectioned ureter into the renal pelvis as a treatment for ureteral stricture. Fenger first applied the Heineke-Mikulicz principle of gastric surgery to ureteral strictures by incising the stricture longitudinally and suturing the incision transversely. Since these pioneering efforts, many modifications and original procedures have been used. Unfortunately success did not always crown their efforts, and it is my belief that disaster of one degree or another has occurred more frequently than the literature would lead us to believe. Ormond has recently written a paper entitled "Unsuccessful Plastic Operations for Hydronephrosis"; and, aside from its general excellence, it is unique in that it stresses the pitfalls attendant upon plastic renal surgery. The glowing reports of several years ago on plastic renal surgery will not, I believe, present as glowing a picture after the lapse of sufficient time for the declaration of all the surgical dividends.

The cause of pelviectasis is a failure of the renal pelvis to properly empty itself. This may be secondary to an obstruction at the ureteropelvic junction by a fibrosis in or about the ureter, an accessory blood vessel adversely situated with relation to the pelvis and ureter, a neurogenic dysfunction of the pelvis, an incorrect attachment of the ureter to the pelvis or an obstruction within the ureter. The problem of obstructive renal pelvis surgery is a problem of correct drainage. The renal pelvis is a relatively inelastic structure relying to a large extent upon dependent drainage. Any interference with this drainage causes a retention of fluid with its resultant enlargement of the pelvis due partially to

*Read before the annual meeting of the Medical Association of Montana, Great Falls, Mont., July 14, 1937.

excretory pressure, but, largely, to the weight of the retained urine. This is especially true of the extra-renal pelvis. Thus the great distortion of a large hydronephrosis shows the ureter attached high on the pelvis in a position making drainage

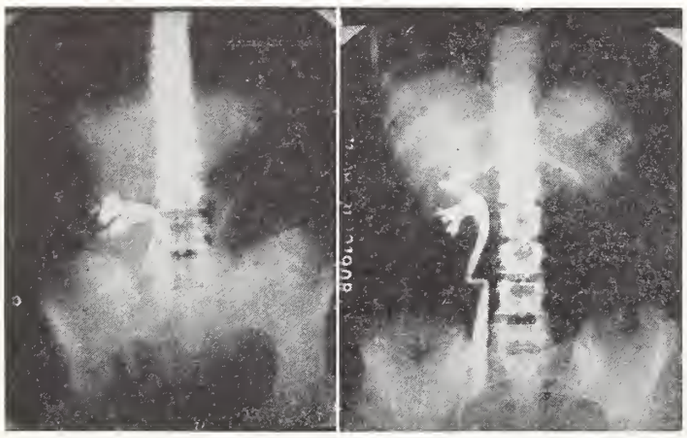

Fig. 1 *(left)*. Retrograde pyelogram of right kidney of forty-eight year old female patient. Complained of severe back and genital pain and recurrent attacks of chills and fever. Renal ptosis, grade 2, with marked ureterectasis.
Fig. 2 *(right)*. Two-months postoperative retrograde pyelogram of same patient. Clinically cured. Operative procedure—nephropexy. Marked improvement in the ureterectasis.

impossible. This non-dependent attachment is a result of the hydronephrosis rather than the cause of it. This is definitely shown in the return of the pelvis to normal or near normal size shortly after the restitution of proper drainage. All of you have seen the prompt reduction in size of a huge hydronephrosis by a properly placed nephrostomy tube. This can be duplicated by any other type of drainage. The important fact is adequate drainage, not the type of drainage. This is a fact that many surgeons have lost sight of in their treatment of hydronephrosis. They have reduced the size of the renal pelvis by resection or by plication, have reimplanted the ureter into the pelvis or have operated upon the uretero-pelvic junction and have neglected the associated or primary cause of the hydronephrosis, e.g., the malposition of the kidney. Many surgeons, on the other hand, have fixed the kidney in a good position in addition to their pelvic surgery but have attributed their good results to the plastic pelvis surgery when it should in a large part, if not entirely, have been attributed to the improved position of the kidney.

Figure 1 shows the pyelogram of a forty-eight year old female patient with renal ptosis of a moderately severe grade having back pains, pain into the genitals and attacks of chills and fever.

Figure 2 shows the same patient two months later. The kidney is held in good position by nephropexy, the calices and pelvis not much changed but the ureter is greatly improved and the patient has no symptoms.

Careful analysis of the good results from plastic operations upon the renal pelvis will show that nephropexy has also been performed in practically all cases. The state of flux which still prevails in renal pelvis surgery is ample evidence of the rather indifferent results the many complicated procedures have had. A few years ago Walters made this statement, "The conservative treatment of hydronephrosis centers around the surgical principle that adequate relief of the obstruction at the uretero-pelvic junction be consummated with a minimal disturbance of renal and ureteral tissue." This becomes increasingly evident to the surgeon as he gains experience in renal surgery. There are, however, many points of renal surgery lost sight of by the individual surgeon in his enthusiasm for a certain type of operation. It is thus most important for the surgeon to first fit his procedure to each case and then to truly evaluate the results on the basis of the procedure or procedures used.

The obstruction of the urinary tract at the bladder neck or at the uretero-vesical junction is a very frequently encountered condition and, while not a part of this paper, must be mentioned because it so frequently complicates the diagnosis. Because unrelieved obstruction anywhere in the urinary tract will ultimately cause ureterectasis, pelviectasis and caliectasis alone or together, the surgeon must be most careful of his diagnosis so as not to operate on a false premise. Careful diagnosis will practically always necessitate retrograde pyelography. Excretory urography alone may be misleading and one may find varying degrees of function even to apparent total non-function of one kidney at one examination only to find an apparently normal functioning kidney at a later examination. When the diagnosis has been made, it is well to reserve judgment as to the exact type of operation to be used until the kidney has been carefully exposed and examined. The final decision as to the procedure to be used must depend upon four factors:

1. The condition of the patient.
2. The condition of the opposite kidney.
3. The condition of the renal parenchyma of the kidney being operated upon.
4. The type of obstruction.

The condition of the patient and of the opposite kidney must both be determined prior to operation through a study of the blood chemistry and the individual kidney functions. Frequently the presence of an excellent kidney on the opposite side may prejudice one to nephrectomy of the involved kidney. This is especially true in the case of an elderly patient unable to stand the financial drain of a long hospitalization and a long convalescence or of an elderly patient in rather poor physical condition. Under such circumstances nephrectomy may be rightly termed the most conservative procedure. In case the kidney is largely destroyed, we are forced to do a nephrectomy unless the opposite kidney is so poor as to demand the saving of all possible renal tissue. Before condemning a kidney as beyond repair, one should remember the tremendous recovery a kidney is capable of making once adequate drainage has been established. A kidney with as little as one-third of its parenchyma intact will recover a life-sustaining function. Two years ago I operated upon a patient with a calculus-obstructed solitary kidney after thirty-six hours of complete anuria. The day following the operation at which the calculus was removed and a nephrostomy performed, the phenolsulphonphthalein excretion was practically nil, the blood urea value was 234 mg. per 100 c.c. of blood and the creatinin value was 9.2 mg. per 100 c.c. of blood. These are usually considered fatal blood chemistry values. In spite of this the patient had only a moderately stormy convalescence and six months later had only slightly elevated blood urea and creatinin values, a phenolsulphonphthalein excretion of over 50 per cent in two hours and was leading an active life. This merely demonstrates what a kidney is capable of doing under the proper conditions of drainage. When the kidney has been exposed and the decision has been made to save it, then the type of procedure will depend upon the type of obstruction present. May I repeat that all good results follow adequate drainage and that, therefore, the simplest method of instituting such drainage must be the method of choice. We must, of course, remove any obstruction which may be present. Frequently, in the case of an aberrant renal blood vessel or a fibrous band of scar tissue, simple excision will suffice. Especially is this true in an early, small hydronephrosis.

Figure 3 is the retrograde pyelogram of a twenty-eight year old female patient with a history of three attacks of severe renal area pain, chills and fever in the past twelve months. Definite obstruction at the uretero-pelvic junction was diagnosed as an aberrant blood vessel prior to operation and was confirmed at operation. Simple excision with nephropexy was performed.

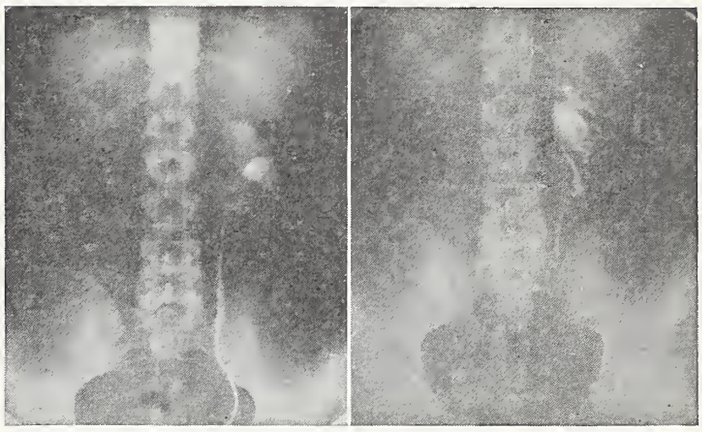

Fig. 3 *(left)*. Retrograde pyelogram of left kidney of twenty-eight year old female patient. Three attacks in past year of severe back pain, chills and fever. Pre-operative diagnosis of aberrant blood vessel obstructing uretero-pelvic junction.
Fig. 4 *(right)*. Fourteen-month postoperative retrograde pyelogram of same patient. Clinical cure. Operative procedure—section of aberrant vessel and nephropexy. Great improvement in the caliectasis and pelviectasis.

Figure 4 is a retrograde pyelogram of the same patient made fourteen months later, showing the tremendous improvement of the kidney. The patient is now completely symptom-free.

In deciding to divide an aberrant blood vessel, one must be certain that the vessel to be severed is not the sole blood supply of a sufficient area to cause necrosis. Obstruction of the vessel for a few minutes will demonstrate, by the change in color of the involved renal tissue, the area supplied by the vessel. The size of this area will determine the procedure to be followed. Hugh Young has said that impairment or serious injury to the kidney produced by ligation of the vessels to the lower pole and the occasionally very imperfect results obtained by ureteral transplantation have brought forcibly to his attention the fact that both of these procedures are far from ideal. He has, therefore, devised an operation in which the pelvis is plicated in such a manner as to draw the ureter away from the aberrant vessel and thus relieve the obstruction. The decision in the presence of large vessels will, of course, vary with the surgeon and must be either this procedure or reimplantation of the ureter. Nephropexy used in conjunction with simple removal of the obstructing mechanism is so simple

as to be almost mandatory. There are many types of nephropexy. One which I described last year is very simple and very efficient in that it permanently fixes the kidney in a high position.

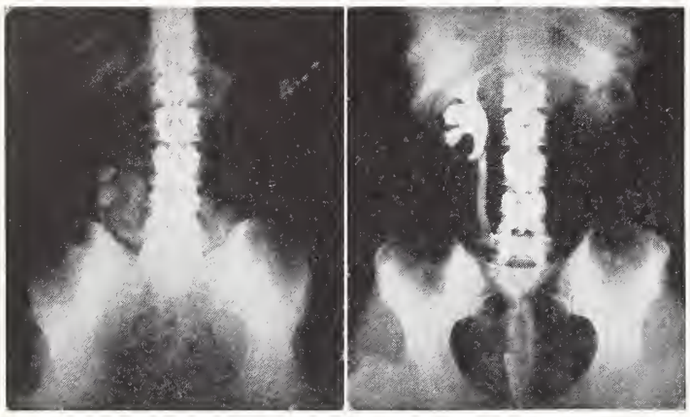

Fig. 5 *(left)*. Retrograde pyelogram of thirty-nine year old patient. Complained of severe back pain relieved on lying down. Renal ptosis, grade 2 plus, with definite caliectasis and ureterectasis.

Fig. 6 *(right)*. Twelve-month postoperative retrograde pyelogram of same patient. Clinical cure. Operative procedure—nephropexy. Marked improvement in caliectasis, especially so in the ureterectasis.

Figures 1, 2 and 5, 6 show the remarkable results simple nephropexy will obtain when no obstructing mechanism is present.

The large hydronephrosis will necessitate a nephrostomy in its treatment. Often in the case of great pelviectasis the uretero-pelvic junction will be attached far up on the pelvic wall. This will frequently influence the surgeon to a pelvic resection or a reimplantation of the ureter; but given a properly fixed kidney, a sufficiently patent uretero-pelvic opening and a well-placed and long-retained nephrostomy tube, and very nearly 100 per cent will drain more perfectly than kidneys that have had reimplanted ureters or a resected pelvis. Should the surgeon feel that the pelvis cannot possibly return to a near normal state without better drainage, then the use of Foley's Y incision and suture of the uretero-pelvic junction will be more efficient than resection and reimplantation of the ureter with its attendant dangers. In all but the most simple cases, nephrostomy is a most important part of the surgical procedure; and in cases involving plastic surgery on the uretero-pelvic junction, it is necessary to use a ureteral catheter as a splint passed into the ureter from above and retained for a long period, as Ormond and Hugh Cabot have recently pointed out.

Obstruction of the ureter may be due to calculus or calculi, to strictures or to fixed kinks. The removal of the calculi is, of course, imperative although associated conditions must also be treated.

Figures 7 and 8 are of a very interesting case. Figure 7 is the ten-minute excretory urogram of a twenty year old girl. She had complained of chills and fever with intense left-sided pain. The left kidney shows marked caliectasis with little or no pelvic or ureteral shadow. The calcified shadows in the lower ureter region are confusing because of the presence of many shadows in the course of the right ureter which with its kidney is normal. A diagnosis of calculi in the lower ureter was made especially as I was unable, because of obstruction, to catheterize the ureter beyond the intravesical portion. At operation the upper shadow was found to be a calculus and was removed. The lower shadow was also a calculus but could not be grasped and removed nor could it be forced into the bladder. The ureter was greatly inflamed and very friable so the wound was closed without removing the lower stone. Eight days later the patient was cystoscoped using a McCarthy panendoscope and the ureteral orifice incised with a Collings knife. The calculus was exposed and flipped into the bladder with the electrode tip. A ureteral catheter was passed to the renal pelvis and left in place two days. An uneventful convalescence occurred. Figure 8 is a retrograde pyelogram eleven months later. The patient is symptom-free, and the pyelogram is quite normal, considering its prior condition.

Strictures of the lower ureter yield themselves very well to dilation. Fixed kinks below the uretero-pelvic junction are rather rare. Liberation of the kinks with nephropexy is usually conducive of good results. Strictures which cannot be dilated must be either incised or excised. Fenger's procedure is moderately successful, although in strictures at the uretero-pelvic junction, Foley's modification of Schwyzer's Y incision will be more satisfactory. Excision of the stricture with resuture using one of several methods of re-establishment of continuity has not been uniformly successful. Von Lichtenberg has never resected a ureteral stricture and repaired it with end-to-end anastomosis because of his fear of later stricture formation. Splinting the ureter with a ureteral catheter drawn through a nephrostomy opening and kept in place an unusually

long time gives the best chance of success and the prevention of secondary stricture formation. In such cases postoperative dilation of the ureter may be necessary.

Uretero-pelvic juncture obstruction requiring surgery is relatively more frequent than ureteral obstructions of similar magnitude. There have been many operations devised for the relief of this obstruction. Many of the originators, as I have stated, ignored the cardinal principles of drainage in their enthusiasm for surgical reconstruction and thus many failures have resulted. Ormond has divided failures into four divisions:

1. Death.
2. Immediate failure of function or immediate complication requiring further treatment, usually nephrectomy.
3. Delayed failure of function necessitating further treatment; again usually nephrectomy.
4. Lack of symptomatic relief.

The causes of failures may be many and varied, but may usually be avoided by proper diagnosis, proper choice of procedure and proper postoperative management. Having performed the plastic procedure upon the renal pelvis, it is well to recognize the fact that dense adhesions will form and that it is, therefore, necessary to prevent ureteral kinking. For this prevention the following procedures are absolutely necessary:

1. Nephrostomy—the correct drainage of the pelvis through the lower portion of the renal cortex with a self-retaining catheter after the method of Cabot and Holland—is greatly superior to pyelostomy.
2. Nephropexy, giving positive fixation in a high position with an unkinked ureter.
3. Adequate perirenal drainage.
4. Splinting of ureter with ureteral catheter drawn out alongside of nephrostomy tube in all cases of reconstruction of the uretero-pelvic junction.

The nephrostomy tube gives perfect drainage and thus promotes shrinkage of the dilated pelvis to a size more closely approaching the normal. It also aids in combating infection by both the improved drainage and by allowing the mechanical flushing of the renal pelvis with antiseptic solution. This reduces the frequency and severity of cortical abscesses, which are one of the great postoperative dangers.

The nephropexy insures the continuance of this adequate drainage through the ureter when

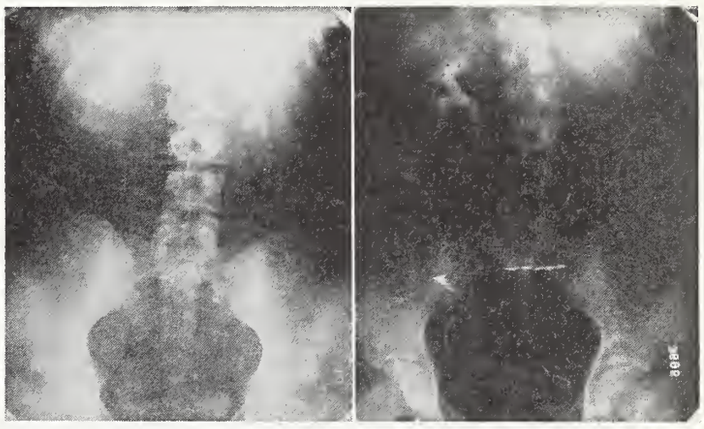

Fig. 7 *(left)*. Ten-minute excretory urogram of twenty year old female patient. Complained of six months' symptoms of pain in left back and side, genital pain, fever, loss of weight. Diagnosis: two calculi in lower left ureter with obstructive hydronephrosis.

Fig. 8 *(right)*. Eleven-month postoperative retrograde pyelogram of same patient. Clinical cure. Operative procedure—removal of calculi. Marked improvement in the caliectasis and pelviectasis with diminution in size of the kidney shadow.

the nephrostomy tube has been removed. Failure to remove the uretero-pelvic junction obstruction will be manifested on removal or clamping of the nephrostomy tube by the symptoms of acute pyelonephritis. This condition necessitates further treatment, usually a reëstablishment of drainage or nephrectomy.

The perirenal drainage is a most necessary procedure because of the frequency, in fact almost constancy, of extravasation of urine about the kidney when the pelvis has been incised. Failure to properly drain may endanger the patient's life and most certainly detract from the beneficial results of the operation. Cabot has mentioned that one of the fundamental precepts of plastic surgery is to prevent scar tissue contracting for three months. After that period it will not contract. He has applied this to plastic work on the uretero-pelvic junction by keeping a ureteral catheter splint in place for a similar period and has succeeded in cases where at a previous operation he failed without this long period of splinting.

There has been a great deal of work done upon the sympathetic nerve supply to the kidney and ureter. Caporale concluded a recent paper with the statement, "Segmentary sympathectomy of the ureter will produce primarily an atony in the tract itself, and secondarily, a gradual peri-

ureteral atony which culminates in a progessive hydro-ureteronephrosis." Sympathectomy also gives the surgeon a temporary false result in that the patient is symptom-free until such times as the increasing hydro-ureteronephrosis, as Caporale names it, becomes of sufficient size or becomes infected sufficiently to cause grave symptoms.

The contentions I have made in this paper were not made to belittle any certain type of operation, but rather to accentuate the need of mature judgment in renal surgery and also in the belief that these contentions are especially applicable to the surgeon of limited experience in renal pelvis surgery. In conclusion, then, conservative renal surgery is dependent upon:

1. Complete and proper diagnosis.
2. Unbiased choice of procedure, determined by individual needs of each case, with the sole idea of instituting proper renal drainage at a minimum of tissue trauma.
3. Nephrostomy in all infected cases, in all large hydronephroses and in all plastic surgery of the renal pelvis.
4. Nephropexy in all cases.
5. Ureteral splinting in all plastic operations of the uretero-pelvic junction and of the ureter proper.

RADIUM TREATMENT OF RARE FORMS OF LEUKEMIA*

ROBERT E. FRICKE, M.D., and CHARLES H. WATKINS, M.D.

Rochester, Minnesota

EVER since the original description of leukemia from the postmortem findings by Bennet and Virchow in 1845 and its clinical recognition by Vogel, a satisfactory method of treating the condition has been anxiously sought. Described as an excessive proliferation of the leukopoietic tissues of the body, either myeloid or lymphoid, with the presence of abnormal leukocytes in the circulating blood, the precise etiology is unknown although the condition may follow malaria or severe pyogenic infection. Certain of the lower animals, such as dogs, horses, cattle and chickens, are susceptible.

Before the advent of irradiation, a large number of remedies were tried. Most of them were toxic and dangerous and few afforded much palliation. Iron and arsenic have been given to combat the anemia, and benzol, quinine, tuberculin, and nuclein have been used to reduce the excessive number of leukocytes. Splenectomy has also been carried out.

These measures were empirical, however, as the true cause of the disease, as has been said, awaits discovery. Hence the therapeutic search has been for methods to afford palliation and relief from the distressing symptoms. In fact, to this day, no palliative treatment has been found for the occasional acute forms of myelogenous or lymphatic leukemia; the disease runs the rapid course of a fulminating overwhelming infection and the outcome is fatal.

In 1903, Nicholas Senn[5] reported gratifying results in the treatment of a patient with chronic myelogenous leukemia by roentgen rays. Rénon, Degrais and Desbouis[4] used radium therapy, and in 1913 reported five cases in which patients were treated by this method. One of the earlier reports in this country (1917) was by Giffin,[2] who reported thirty cases in which radium treatment was employed.

Since this early work, roentgen and radium

TABLE I. RADIUM TREATMENT OF RARE FORMS OF LEUKEMIA
Symptoms, diagnosis and results

Case	Age, years, and sex	Admitted	Diagnosis	Symptoms	Results
1	41 F	4-18-35	Subleukemic splenic reticulo-endotheliosis	Nosebleeds (6 mos.). Mass ULQ (6 wks.). Tired easily (2 mos.)	Dismissed 12-10-36. Good general condition
2	50 M	4-25-35	Chronic leukopenic myelogenous leukemia	Swelling left abdomen (3 mos.). Shortness of breath after meals	Fair palliation. Returned 2-37 with enlarged spleen. Condition fair
3	46 F	5-20-35	Subleukemic splenic reticulo-endotheliosis	Tired, weak (5 years.). Enlarged spleen (2 yrs.). Anemia. Spleen 3*	Excellent response and palliation to date
4	49 F	7- 8-36	Chronic leukopenic myelogenous leukemia	Mass ULQ (3 mos.). Discomfort	Much palliation. Improved blood count. Seen 12-4-36, no treatment needed
5	57 F	11-23-36	Subacute lymphatic leukemia	Weak, tired, short of breath, edema of ankles (4 mos.). Spleen 3+,* general glandular enlargement	Remarkable remission. Count practically normal. Dismissed 12-18-36
6	37 M	1- 6-36	Subacute lymphatic leukemia	Weakness, dyspnea (2 yrs.). Spleen 3+*	Spleen reduced, WBC 7,800. Dismissed 1-16-36
7	70 M	6- 4-36	Chronic leukopenic myelogenous leukemia	Anemia (5 to 6 yrs.). Weak, short of breath, lost weight (1 yr.). Spleen 3*	Letter (9-2-36): "Reached home comfortably"
8	47 M	5- 7-36	Chronic leukopenic myelogenous leukemia	Chills, fever, cough, "flu," vertigo, pain in bones (6 mos.). Spleen 3*	Spleen softened and reduced
9	39 M	10-22-36	Acute leukemic reticulo-endotheliosis	Acute tonsilitis. Acute cerv. adenitis (4 wks.); became generalized	Course rapidly downhill. Dismissed 10-29-36. Died 11-1-36
10	61 M	6-18-36	Monocytic leukemia, Naegeli type, subacute	Weakness, loss of weight, inability to work (6 mos.)	Dismissed November, 1936; several transfusions elsewhere
11	58 M	11- 2-35	Subleukemic splenic reticulo-endotheliosis	Splenomegaly, petechiae, asthenia following erysipelas	Dismissed 11-20-35, 3-26-36: patient up and around, much improved
12	40 F	6-24-35	Chronic myelogenous leukemia, leukopenic type	Pain and swelling of joints (1 yr.). Vertigo and weakness (7 mos.)	Re-examined 3-4-36. Much better. Arthritis improved
13	3 M	11- 2-36	Leukemic reticulo-endotheliosis	Age 5 mos.: extensive skin infiltration, WBC 300,000, spleen 3.* On admission: swelling right eye, spleen palpable, general glandular involvement	Improved. Letter (12-8-36): doing well, residual pain in ankle and knee joints
14	33 M	3-26-34	Chronic myelogenous leukemia (leukopenic type), low grade	Spring 1933, operated on for appendicitis and cholecystitis. Spleen 2.* Diarrhea and bleeding rectum (8 mos.)	Letter (11-13-36): Much better spleen smaller
15	61 M	11- 5-35	Leukemic reticulo-endotheliosis	Short of breath, weak (1 mo.)	Indeterminate
16	64 M	6-21-35	Chronic leukopenic myelogenous leukemia	Weakness (2 yrs.). Mass abdomen (6 mos.). Dizziness, pallor and dyspnea	Good palliation. Dismissed 4-14-36. Died 8-7-36

*Grade of enlargement.

therapy have been universally accepted as the preferable form of treatment for chronic myeloid or lymphatic leukemia. The beneficial effect, however, has been entirely in the realm of palliation. Exact evaluation of this is difficult because of the natural spontaneous remissions which occur in a very small percentage of cases in which patients are untreated. We have observed no permanent cures following irradiation. One of us (Fricke[1]) reported the results of the radium treatment of 157 patients with leukemia and found no prolongation of life of those treated as contrasted with those who were not treated; the palliation secured, however, was definite and impressive. In nearly all cases the symptoms disappeared completely and the patients were able to resume their normal activities for months at a time.

Typical leukemia is a relatively infrequent disease, Barker having said that there were only one or two leukemic patients in every thousand admissions in general hospital practice. The disease occurs at any age, although it is more frequent in middle life. Males are more often affected than females. The chronic forms of the disease are, fortunately, more common than the acute forms, and chronic myelogenous leukemia is more frequently seen than lymphatic leukemia. Irradiation affords slightly more pronounced palliation in cases of chronic myelogenous leukemia.

In this study we are considering the more unusual or borderline types of this rare disease, and these demand, for their detection, a careful study of the history, physical examination, blood studies, and particularly, care in the recognition of immature blood cells. Many of these aleukemic or leukopenic types of leukemia present as their initial symptom, anemia with a leukocyte count within normal limits or even low, which, in association with splenomegaly, may be confused with splenic anemia or Banti's syndrome. Many times purpuric manifestations will appear relatively early in the disease, and in the presence of an unexplained anemia with purpuric manifestations and a normal leukocyte count, one should make a thorough search for immature cells in the blood. One of us (Watkins[6]) has called attention to the differential diagnosis of these conditions. In our experience these atypical leukemias have frequently been confused with Banti's syndrome and agranulocytosis.

If the incidence of ordinary leukemia is one or two in every thousand general hospital admissions, there will be found one or two of these borderline types to every hundred cases of leukemia. The diagnosis of these rarer types is improving and more cases are being reported each year. These unusual types of leukemia may be classed as aleukemic phases of myelogenous, lymphatic, monocytic or leukemic reticulo-endotheliosis.

One type of particular interest is subleukemic splenic reticulo-endotheliosis, which was described by Giffin and Watkins[3] in 1934. In the two cases reported at that time, splenectomy was performed, with only temporary improvement in the patients' condition. Since then six other cases of this type have been recognized and the patients treated by radium, with quite satisfactory results. The longest duration of life to date, in this group of patients treated by radium, has been two years, and the patients have remained in very good condition. It seems that, in most of these cases, radium decreases the size of the spleen, enables the patient to maintain a more nearly normal leukocyte count, and reduces the number of immature cells in the blood. It is not the purpose of this paper, however, to discuss in detail the diagnosis of the condition except to say that it is finally established by the finding of monocytes showing characteristics of reticular origin in the circulating blood. For detailed discussion, one is referred to the article just mentioned.

During 1935 and 1936 we have treated, with radium, sixteen patients with these atypical leukemias (Tables I and II). Of these sixteen patients, ten were males and six females. They ranged in age from three to seventy years, the average age being forty-seven. Eight patients were diagnosed as having aleukemic phases of chronic myelogenous or lymphatic leukemia (in only two of these eight cases was it of the lymphatic type). One patient had a monocytic leukemia of the Naegeli type, and seven, types of reticulo-endotheliosis. We believe that once the diagnosis is established in these obscure cases with low leukocyte counts, radium is the treatment of choice in order to obtain satisfactory palliation. Roentgen therapy covers a larg-

er portal and the effect of treatment is usually too sudden and drastic. Our best results have been obtained by the very cautious and well-controlled use of radium.

At a distance of 1 inch (2.5 cm.) from the skin, 50 mg. of radium sulphate (element), filtered through 2 mm. of lead, was applied for a period of eight to twelve hours, depending on the leukocyte count, the size of the spleen and the general condition of the patient. In addition to daily blood counts, blood smears were studied in detail and the amount of destruction of immature cells was noted. Should there be evidence of a decrease in the leukocyte count or an increase in the degree of anemia, radium treatment is stopped for a while until the blood count returns to its previous level. It is quite the rule that in most of these cases of low leukocyte count there is an increase in the erythrocyte count following treatment with radium. The anemia is practically corrected within a relatively short time and the immature cells of the leukocytes series are gradually eliminated. The differential count usually approaches a more nearly normal level.

The patients were then sent home for three or four months. Treatments varied from one to nine areas over the spleen in one treatment series, and from eight to twelve hours of treatment per area, all carefully controlled by blood counts.

Fifteen of the sixteen patients showed improvement in the condition of their blood and amelioration in their symptoms (Table I). The one exception was a man, aged thirty-nine years, who suffered from an acute reticulo-endotheliosis following a severe attack of acute tonsillitis four weeks previously. Radium treatment was begun, but was abandoned after twelve hours, as the patient was failing rapidly. He died two days later. Too little treatment was applied to have affected the disease one way or another.

Summary and Conclusions

The ability to recognize immature cells is the first requisite in establishing the diagnosis of these rare forms of leukemia. These cases are seldom seen, but they are important and better diagnosis will increase the number that are recognized.

In the differential diagnosis many diseases have to be ruled out, such as aplastic anemia, purpura hemorrhagica, agranulocytosis, Banti's syndrome and hemolytic jaundice. In these conditions, irradiation is not only contraindicated but likely to prove decidedly injurious.

In the treatment of these rare types of leukemia, splenectomy, which has been occasionally performed, does not help. Roentgen therapy, often covering portals which are too large and including too much of the blood-forming apparatus, is too drastic and may prove harmful. The best therapeutic agent seems to be cautious, limited radium treatment. It has, in our experience, proved of great value in producing effectual palliation.

TUBERCULOUS INFECTION AND MORBIDITY AMONG MEDICAL STUDENTS AND PHYSICIANS*

FRANK L. JENNINGS, M.D., F.A.C.P.
Oak Terrace, Minnesota

TUBERCULOSIS is still so prevalent a disease that it is encountered by every physician and medical student whether he is aware of the contact or not. Whether this contact can be considered an occupational hazard is a question that has been of great interest to us at Glen Lake Sanatorium because medical students from the University of Minnesota come here for their instruction in tuberculosis. In examining these students upon entrance, we were at first chiefly interested in the study of pathological lesions of tuberculous origin and their clinical activity, but more recently we have included the study of tuberculous infection.

Infection

Fourth year medical students have each spent two weeks as clinical clerks in this sanatorium since 1925. In 1929, we first began to question them in regard to tuberculin tests† given them before they came to us. We found that of the first eighty-seven students questioned, fifty-seven (65 per cent) had reacted positively when tested at the Students' Health Service at the University to 1:1000 dilution of old tuberculin. We felt, however, that more exact information could be obtained if we tested all students the day they came to the Sanatorium. Therefore, beginning in the middle of November, 1930, the next 184 students were tested and 122 (66.3 per cent) were found to be positive to the intradermic test.

Because our percentages in these two groups were so close, we decided in June, 1932, to question the students and test only those who gave a history of not reacting to tuberculin. We felt this method would give us very satisfactory results because the medical students of the University of Minnesota have been made intelligently aware of the importance of present day methods of detection, prevention and treatment of tuberculous disease through the interest in this subject of Dr. J. A. Myers and Dr. H. S. Diehl. Our findings by the year are shown in Table I.

TABLE I. THE INCIDENCE OF POSITIVE AND NEGATIVE TUBERCULIN REACTIONS

(Among students entering the Sanatorium for study)

Year	Negative	Positive	Questionable or no Record	Per Cent Positive
1930	36	80	4	66.6
1931	38	71	1	64.5
1932	53	90	–	62.9
1933	56	64	2	52.5
1934	39	85	2	67.4
1935	55	62	1	52.5
1936	36	76	–	67.8
	313	528	10	62.04

It will be noted from this table that the range of positive reactors to tuberculin varies for the different years from 52.5 to 67.8 per cent. The average of 62.04 per cent among our 851 fourth year medical students is less than that reported among fourth year medical students in the eastern part of the country. At the University of Pennsylvania,[3] it was found that the number of positive reactors among their medical students increased in each year of the course until in their fourth year 98 per cent of them reacted positively. It was observed that this steady increase in the number of reactors (noticed also at Yale) is not necessarily confined to medical schools, but is probably true of any school where the students' opportunities for infection must increase with continued residence among a large

*From the Department of Medicine, University of Minnesota, Minneapolis, and Glen Lake Sanatorium, Oak Terrace, Minnesota.

†These students had for the most part been examined at the Students' Health Service within a year prior to coming to the Sanatorium and all students who had been negative to tuberculin at this Health Service examination were re-tested. Old tuberculin was the substance used at the University. At Glen Lake, we used from November, 1930, to March, 1932, Dorset's Old Tuberculin, .01 mg. on one arm and MA 100 Human Tuberculin .0005 mg. on the other arm. Those who reacted negatively to the above doses were given a double dose of MA 100. Beginning in March of 1932, only MA 100 Tuberculin was given until December, 1934, when PPD was started and we have continued to use the latter to date. When we first started using PPD, we used both strengths, but during the past year only the second strength (0.005 mg.) has been given.

group of people. Similarly, 91 per cent of the fourth year students at Johns Hopkins[2] had positive reactions, as did 94.1 per cent among the three upper classes in medical school at Yale.[6] It is probable that the lower incidence among our students as compared with that of these other schools lies in the fact that our sudents, for the most part, come from communities less densely settled than do the students attending eastern schools. This lower incidence of tuberculous infection among college students (mostly non-medical) in the Middle West has recently been observed by Long and Seibert,[4] who also think that the above explanation is the most logical.

Morbidity

The incidence of morbidity among medical students is of equal or greater interest than that of infection. In an effort to obtain facts about the morbidity among our fourth year medical students when they came to the sanatorium, as well as subsequent to their stay here, the following data were accumulated.

Since 1920, medical students from the University of Minnesota have been coming to Glen Lake Sanatorium, an institution caring for 700 patients, for their instruction in the treatment of tuberculosis. Until about 1923, the period of study equalled three months. This time was gradually shortened until it was set at two weeks in 1925. Since then, all the members of each fourth year class have been in residence here for two-week periods of instruction. Their work has consisted of taking histories, making physical examinations, and in helping with various forms of treatment both in the wards and in the treatment rooms. In short, they have been in contact with tuberculous patients during those two weeks to the same degree as have the resident sanatorium physicians.

The possibility of tuberculous disease was taken into consideration from the first, and x-ray films were made of the students' chests the day they started work at the sanatorium. The present study is a review of those films in connection with a questionnaire sent to the former students. The period here covered is the first ten years of this plan, extending from 1920 to September 15, 1930. To the 670 in this group who had been here for training at some time during the ten years, questionnaires were sent early in 1932 in an attempt to ascertain the state of their health during the interval between receipt of this questionnaire and their sanatorium residence. Replies were received from 526, or 78.6 per cent of the group.

These replies have been classified into two main groups: the normal and the abnormal, depending upon the interpretations of the chest x-rays taken when these people first came to the sanatorium. The normal group, numbering 473, consisted of those whose interpretations were described as any of the following: normal chest, increased bronchial markings, slight thickening of the pleura. The abnormal group consisted of those whose interpretations might constitute possible evidence of tuberculosis or tuberculous infection, such as definite infiltration, primary complex, fibrosis of the parenchyma. There were fifty-three in the latter group.

Normal Group

267 had no subsequent x-rays
206 had subsequent x-rays

473 total

The replies to the questionnaire disclosed that 267 of the normal group of 473 had considered themselves in good condition and had not troubled to have subsequent x-rays of their chests. Of the 206 who had had subsequent x-rays, 168 still had normal readings. Thirty others reported abnormal findings consisting of evidence of acute or chronic non-tuberculous conditions variously diagnosed as bronchitis, bronchiectasis, emphysema, et cetera, but no evidence of adult tuberculosis. Briefly there were 465 of this group who had shown no subsequent evidence of tuberculous disease.

The remaining eight in this group whose roentgen findings were considered normal when they were here as students subsequently showed lesions of pulmonary tuberculosis. In two of them, the disease was diagnosed as far advanced, in two others moderately advanced, and in three as minimal. The one remaining case was classed as questionable. Their lesions had all appeared in from one to four years after their training at the sanatorium, but it must be remembered that during that interval they were practicing their profession and had come in contact with all types of patients. Five of these physicians reported at the time of the questionnaire that they were

working and a sixth reported that he expected to return to work in a short time.

Abnormal Group

39 had subsequent x-rays
14 had no subsequent x-rays

53 total

Ten per cent (fifty-three) of the students who came to the sanatorium showed deviations from the normal that might constitute possible evidence of tuberculosis when their chests were first examined. The answers to the questionnaire that was sent to these students one to ten years after their period of instruction at the sanatorium showed that thirty-nine had had subsequent x-ray examinations. This group of thirty-nine is divided as follows: thirty-three who had shown no clinical evidence of tuberculosis and six who had shown definite evidence of clinical tuberculuosis when they were in residence here. Considering the thirty-three, we find that twenty of them reported that their lesions had shown no change from the examinations made at the sanatorium. Their lesions were divided as follows: two with Ghon tubercles; seventeen with fibroid lesions (six bilateral and eleven unilateral); one with unilateral artificial pneumothorax. Ten of the thirty-three had had subsequent roentgenograms of the chest that had been interpreted as normal. In reviewing the films taken when these ten first came to the sanatorium, we found that eight of them at that time had shown a slight fibroid change in one or both apices and two of them had shown primary complexes. In the three remaining cases of the thirty-three, one showed definite improvement in a bilateral lesion and the two others reported slight fibroid lesions on the opposite side from those found while at the sanatorium.

There were six cases in this abnormal group who had shown specific evidence of tuberculosis when they came to the sanatorium as students. Five of the six had shown definite roentgen changes in the chest. Four of the five had had definite physical findings when first examined. Because of the extent of their disease, two of this group were advised to stop their courses and take up treatment when first seen. The advice was not followed. Four of these five have since shown extension of their lesions and two of them have spent some time in a sanatorium as patients. The fifth case reports malaise but no extension of his lesion and he has never given up work. Four of the five were working when the questionnaires were returned. The sixth one, who showed clinical evidence of tuberculosis and was therefore put in this group, had a normal chest x-ray when he came here for instruction, and this has remained normal to date. However, tuberculosis of the kidney was first definitely diagnosed when he came here as a student, and careful history revealed that it dated back for a period of about two years. The kidney has since been removed and he is now well and working.

We reviewed the films that were made at this institution of the fourteen doctors in this abnormal group who had had no subsequent films taken and found that ten had slight fibroid lesions (seven unilateral and three bilateral) when they came here as students, and four others had shown Ghon tubercles. Forty-seven of the fifty-three students in this group had shown no evidence of clinical tuberculosis subsequent to their graduation.

We were disappointed in that our questionnaire did not aid us in the question of infection as well as in the problem of morbidity. We found that so few of the doctors had had tuberculin tests after they were graduated that the results were of no material value. It is of interest to note that of the approximate 100 who had had tuberculin tests since leaving the sanatorium, 23 per cent were still negative.

After reviewing the literature of morbidity of tuberculosis, Herman, Baetjer, and Doull[2] stated that in their opinion the proportion of symptomatic tuberculosis in males in the general population between the ages of twenty and twenty-nine years is probably not lower than one or higher than three per cent. Our study of a similar age group (23 to 29) brings out that fourteen students out of a total of 526, or 2.6 per cent, showed definite evidence of tuberculosis. Six showed evidence of advanced tuberculosis when first seen and eight developed tuberculosis from two to twelve years after graduation. Steidl,[7] who in 1932 followed medical students in a manner similar to ours, found that 2.5 per cent of the Harvard medical students developed tuberculosis; about half of these developed the disease before graduation, and in a similar follow-up study on the law students found that 2.08 per cent developed tuberculosis. The incidence of

pulmonary tuberculosis in various schools in the University of Michigan from 1917 to 1930 is cited by Herman, Baetjer and Doull,[2] who think that from a statistical point of view the incidence of 2.81 per 1,000 student years found in the medical school is not significantly different from that found in literature, law, engineering and the various other schools in the same university. These figures all compare favorably with ours and do not suggest that the possibilities of developing clinical tuberculosis are greatly increased by a training in a tuberculosis sanatorium as might be inferred from an article by Myers.[5]

Mortality

At the conclusion of this study, there had been no deaths from tuberculosis among the 526 who trained here. Tuberculosis has never caused a proportionately large number of deaths among physicians. Emerson and Hughes[1] found that the tuberculosis death rate among physicians was 39.5 per 100,000 as compared with 133.5 among all white males in the United States. I believe that it is safe to assume that physicians have always been more or less exposed to tuberculosis, but statistics do not show a high death rate among them, which seems to support the assumption that there is a relatively low morbidity rate.

This study reveals: (1) That 62.04 per cent of our fourth year medical students have been infected with tubercle bacilli prior to coming into known contact with tuberculous patients; (2) that the morbidity over a one to ten year period was 2.6 per cent; (3) that there were no deaths among the 526 students who had been here for a period of study. It does not suggest that tuberculosis can be considered an occupation hazard for medical students and doctors.

CLINICAL NOTES ON THE RESULTS OF FEVER THERAPY*

Report of the First International Conference on Fever Therapy New York City, March 29-31, 1937

FRANK H. KRUSEN, M.D.

Rochester, Minnesota

ON MARCH 29, 1937, a group of approximately 250 physicians, including representatives from twenty-nine foreign countries, gathered together at Columbia University Medical School to discuss the present status of fever therapy. During the ensuing three days approximately sixty papers on various phases of fever therapy were presented.

In opening the session, Whipple, of New York, expressed the opinion that fever therapy, although young, still had had an astonishing growth, that hazards might be connected with this remarkable growth, but that he was certain fever therapy had established "new standards in medicine." In reply, Abrami, of Paris, who was Chairman of the French Delegation, extended felicitations and reviewed the early developments in the field with special reference to the original work of Wagner-Jauregg on malaria. A message from D'Arsonval, of Paris, described his early studies on electric heating of the human body that led to the development of physical devices for producing fever. He stated he was proud to have written in 1882 "that the therapeutics of the future will employ as a curative means the physical modificators, heat, light, electricity, and other agents still unknown."

A message was also sent to the Congress by Wagner-Jauregg, of Vienna. He stated that he started his first attempts to treat diseases by means of artificial fever in 1891, when he used injections of tuberculin in the treatment of mental diseases. Since 1900, his studies have been primarily concerned with the treatment of gen-

*From the Section on Physical Therapy, The Mayo Clinic, Rochester, Minnesota.

eral paralysis of the insane. He expressed the opinion that high temperatures, per se, do not produce the beneficial effects in dementia paralytica and he urged that malarial therapy always be combined with chemotherapy in the treatment of this disease. He concluded: "It should not be the aim of these combined therapeutic methods to destroy the pathogenic organism in the human body, but to improve the resistance of the organism and tissues against the pathogenic agents."

Abrami compared the effects produced by the two distinctly different methods of production of artificial fever (injections of foreign proteins and production by physical means). He felt that it was remarkable that two methods so different in nature could produce similar therapeutic results. He felt that physically induced fevers had the advantage of less danger "owing to the fact that the temperature can be controlled and measured accurately."

Richet, of Paris, like Abrami, compared the two chief forms of production of fever. Fevers produced by inoculations with infectious organisms or injections of foreign proteins he called "active fevers" while those produced by various physical means he termed "passive fevers." He felt that the effects were not entirely the same.

Hardy, of New York, studied the mechanism of heat loss from the human body in a calorimeter and concluded that "the mechanism for heat loss is adequate to care for twelve times the basal heat production" and that "spontaneous fever is due almost entirely to malfunction of the mechanism for heat loss."

Halphen and Auclair, of Paris, reported on the treatment of 3,000 patients suffering from various diseases. They produced fever by means of short radio waves and expressed the opinion that "it is regrettable that the American authors should have abandoned short waves in fever treatment without having drawn from it all that it could give." They suggested that the technic which they had developed would prove ideal for the production of fever.

Binet, of Paris, and Gernez of Lille, in studies on the physiology of fever, found great modifications in the antibodies of normal and syphilitic individuals following fever.

Gibson, Kopp and Evans, of Boston, studied the changes in plasma and total blood volume during the course of fever treatment. They concluded that fever unaccompanied by sweating does not, in itself, bring about any considerable changes in blood volume but that when fever is accompanied by profuse perspiration, the reduction in blood plasma may be so great as to produce peripheral vascular collapse. Absorption of fluid from the intestinal tract may be retarded during high fever but intravenous administration of fluids permits rapid restoration of blood volume.

Pijoan, Kopp and Gibson, of Boston, studied the acid-base balance during therapeutic fever and concluded that fever characterized by severe dehydration and hyperventilation brought about a pronounced alkalosis; the degree of alkalosis, which approached critical levels, is dependent primarily on the severity of the dehydration and secondarily on the extent of hyperventilation.

Warren, of Rochester, New York, in seven cases noted the development of jaundice following prolonged fever therapy. He found two significant facts common to each case: (1) the rise in icteric index was accompanied by low value for the serum chloride and diminished excretion of urinary chlorides, and (2) the jaundice was relieved *only* by the administration of large amounts of sodium chloride (as much as 20 gm. in twenty-four hours) and not by the administration of carbohydrates. Proper attention to chloride and water balance "is apparently the most important factor in the technic of administering prolonged fevers."

Doan, of Columbus, Ohio, in an exhaustive study of the differential reaction of bone marrow, connective tissue and lymph nodes to hyperpyrexia, concluded that "hyperthermia by physical means not only provides the thermal factor of importance for the inactivation of the treponema pallidum and the gonococcus but has now been demonstrated to exert a profound effect on the cellular equilibria of the body in the directions which we believe at the present time to be the most effective in the mobilization of the defense forces of the body against these diseases."

Hartman, of Detroit, pointed out that untoward results of fever therapy are "always preceded by cyanosis and vascular collapse" and that it seems justifiable to place anoxemia as the

underlying cause of the lesions found at necropsy following deaths from fever therapy.

Ebaugh, Barnacle and Ewalt, of Denver, concluded that most delirium, seen during fever therapy, could be handled by simple psychotherapeutic and physical procedures. They felt that the administration of sedatives contributed largely to the production of delirious episodes. They concluded that schizophrenia was not benefited by fever therapy. They reported on eighty-seven cases of general paresis; 71 per cent of the patients who were treated with combined physical fever and tryparsamide were benefited while 58 per cent of those who were treated with malarial therapy likewise were helped. As to the cerebrospinal fluid, 52 per cent of the patients who were treated with physical fever and tryparsamide were improved or reversed while 39.5 per cent of those who were treated with malarial fever were affected in the same manner.

Dowdy and Hartman, of Detroit, found that in fever therapy carbamide sedatives were more satisfactory for basic sedation than the barbituric acid group of drugs. They also recommended the prescribing of a high carbohydrate meal on the night before fever treatment and the intravenous injection of 500 c.c. of 10 per cent solution of dextrose in physiologic saline solution on the morning of treatment.

Pamboukis, of Athens, Greece, proposed the use of dengue fever as a therapeutic agent.

Simmons and Dunn, of Omaha, Nebraska, reported fifteen cases of acute rheumatic fever in which fever therapy was employed. Thirteen patients obtained complete relief of pain and swelling of the joints; two patients had relapses within two weeks to two months and one patient had a recurrence of chorea twenty-one months after treatment. In many of the cases, leukocyte counts and sedimentation times became normal after fever therapy.

Osborne, Blatt and Neymann, of Chicago, treated twenty-five children, who had chorea, by means of electropyrexia. Choreiform movements ceased in 88 per cent of the cases. The presence of rheumatic carditis did not preclude the use of fever therapy.

Sutton and Dodge, of New York, reported on the treatment of more than 400 attacks of chorea by means of fever therapy. Sixteen patients who had associated rheumatic carditis were all benefited. A comparative analysis of ninety-five cases in which fever therapy was used and seventy-five cases in which fever therapy was not used showed a definitely lower incidence of rheumatic manifestations in the cases in which fever therapy was used. Fever therapy was capable of cutting short an attack of chorea; the presence of active carditis was not a contraindication to its use but carditis was perhaps benefited by it. Barnacle, Ewalt and Ebaugh, of Denver, during a two-year study, treated forty-five patients who had chorea. Immediate results were excellent and recovery occurred in the majority of cases. There were three recurrences. The incidence of carditis was 42 per cent (nineteen cases). Its presence did not interfere with treatment and two-thirds of the patients who had carditis showed at least an improvement in cardiac function.

Alajouanine and Maruiac, of Paris, concluded that in neurologic practice fever therapy was most beneficial in the treatment of syphilitic disease of the nervous system.

Claude and Rubenovitch, of Paris, advised malarial inoculations followed by prolonged chemotherapy in most cases of general paralysis. They suggested that electropyrexia should be preferred in cases in which Wassermann-fast reactions were present, in cases in which malarial therapy was either contraindicated or had failed, and finally, to reinforce the effect of postmalarial chemotherapy.

Bennett and Cash, of Omaha, Nebraska, recommended fevers at low temperatures as a safe and efficient means of treating neuritic and radicular pains. Hambresin, of Brussels, recommended fever therapy particularly in the treatment of syphilitic optic atrophy as well as in keratitis, iritis and iridocyclitis.

McGavic, of Cincinnati, reported on forty-two cases in which various ocular diseases were treated with fever therapy. Best results were obtained in syphilitic interstitial keratitis while good results also were obtained in gonorrheal ophthalmia and syphilitic iridocyclitis.

Moench, of New York, found that at temperatures ranging from 40° to 42° C. all strains of the meningococcus studied, except one, showed reduction of growth within five to seven hours. Five strains were either destroyed or greatly reduced in five hours or less. She concluded

that fever therapy seems worthy of trial in selected cases of meningococcic infection.

Lardennois, of Paris, thought that fever therapy might benefit localized acute infections.

Major, Doub, and Hartman, of Detroit, studied the effect of fever therapy upon dogs which had been subjected to experimental tuberculosis. Temporary improvement was noted and, as compared with control dogs, life was prolonged.

Jares, of Rochester, New York, studied the thermal death time of animal tumor cells in vitro. He concluded that the combined effects of fever and roentgen rays are superior to the effect of either alone. The most destructive combination was simple fractional roentgen ray dosage (about 300 r. daily) plus heat treatment immediately afterward. Stecher and Solomon, of Cleveland, reported that of twenty patients who had acute nonspecific infectious arthritis, twelve obtained prompt relief and apparent cure while eight were partially relieved.

Walthard, of Geneva, Switzerland, observed the effect of short wave fever therapy in twelve cases of multiple sclerosis. He noted temporary diminution of spastic symptoms during and after treatment. The spasticity reappeared in all cases three or four months after treatment.

Russell, of London, reported fifteen cases in which disseminated sclerosis was treated by fever therapy. In four cases the gait became worse, in five cases there was no change and in six cases there was improvement.

Schroeder, of Copenhagen, recommended the use of intramuscular injections of 0.5 to 2 per cent sulphurated oil as a fever-creating agent.

Bessemans, of Ghent, Belgium, concluded that the best antisyphilitic hyperthermic methods are those which present all the sites of infection for the longest possible time to the highest possible temperature.

Hinsie and Blalock, of New York, reported the results of a twelve-year serologic study of general paralysis. They treated patients by four methods: (1) malarial therapy alone, (2) malarial therapy plus chemotherapy, (3) physical fever alone, and (4) physical fever plus chemotherapy. They concluded that physical fever plus chemotherapy gave the best results in their series of 326 cases. Ten years after treatment the Wassermann reaction on the serum was negative in 75 per cent of twenty-eight cases; in 89.3 per cent of twenty-eight cases the Wassermann reaction on the cerebrospinal fluid was negative; in 100 per cent of twenty-six cases the cell count of the spinal fluid was normal; in 75 per cent of twenty-four cases the globulin reaction was normal, and in 73.1 per cent of twenty-six cases the gold sol curves were normal.

Gourgerot and Durel, of Paris, said that in cutaneous syphilis clinical experiments made thus far have given indisputable evidence of beneficial results with fever therapy, especially when combined with chemotherapy.

Menagh, of Detroit, reported on six months' experience with a mixed group of ninety-nine syphilitics treated with hyperpyrexia combined with chemotherapy. Fifty-four per cent showed improvement, 43 per cent were unimproved and two were not followed. Artificial fever by physical means showed a superiority over malarial therapy only when a satisfactory degree of fever could not be produced with malaria.

Simpson and Kendell, of Dayton, Ohio, in an experimental study of the treatment of thirty-four patients who had early syphilis, by means of artificial fever combined with chemotherapy, said that their observations appeared to indicate that artificial fever fortifies and intensifies the curative action of chemotherapeutic agents and that the time required for treatment can be greatly reduced.

Neymann, of Chicago, in a comparison of 3,000 collected cases in which general paralysis was treated with malarial therapy and nearly 1,000 collected cases in which general paralysis was treated with physical fever, concluded that physical fever has increased the total rate of improvement by 21 per cent and decreased the death rate from between 10 and 30 per cent to a degree which rendered it "no longer a problem." Neymann recommended the use of fever therapy as an adjunct in the treatment of early syphilis.

Kitchevatz, of Belgrade, Jugoslavia, recommended the use of fever therapy produced by means of antistreptobacillary vaccine in the treatment of soft chancre. He felt that it caused improvement and healing of the local manifestations and shortened the duration of the disease.

Ducoste, of Villejuif, France, recommended intracerebral malarial injections in the treatment

of general paralysis. Of 435 paralytics treated by this method in the last ten years, 353 (80 per cent) "have been cured." Failures occurred in 12.8 per cent of cases and there were twenty-six deaths (6 per cent).

Janet and Dreyfus, of Paris, concluded that in gonorrhea the main characteristics of regional hyperthermic treatment were: (1) the striking rapidity of the cure, and (2) the easy management and innocuousness of this therapy. Carpenter and Boak, of Rochester, New York reported on the thermal death time of 250 strains of Neisseria gonorrhœæ at a temperature of 41.5° C. The heat resistance of the gonococcus varied between six and thirty-four hours; the mean was sixteen and one-tenth hours with a standard deviation of four and eight-tenths hours.

Warren, of Rochester, New York, presented an analysis of 163 cases in which gonorrheal infections were treated with fever for periods of time less than the thermal death time of the infecting strain of gonococcus. The length of treatment at 41.5° C. might be as long as 85 per cent of the thermal death time and still fail to result in a cure, while, on the other hand, treatments as short as 10 per cent of the thermal death time occasionally result in cure. Warren concluded that the variation is probably influenced by the defensive mechanism of the body.

Bierman and Horowitz, of New York, have devised a combined local and general heating technic for the treatment of gonorrhea in women. They reported that, during the past six years, of 121 women who were treated by this method the results proved successful in 113 (93 per cent).

Krusen, Stuhler and Randall, of Rochester, Minnesota, reported that of 361 patients who had gonorrhea and were given six to twelve hours fever at 106.7° F., 68 per cent obtained negative cultures and 74 per cent showed improvement. Of 266 patients who had positive cultures and completed treatment satisfactorily, 246 (92.5 per cent) obtained negative cultures. Of forty-one patients subjected to a single ten-hour session of fever, thirty-six (87.8 per cent) obtained negative cultures and three more patients obtained negative cultures after an additional treatment.

Belt and Folkenberg, of Los Angeles, reported on the treatment of sixty-four patients who had gonorrhea, with a single ten-hour fever at 106.8° F. Fifty-nine, or 92.2 per cent, were found to have been constantly free from organisms following the ten-hour session of fever.

Parsons, Bowman and Plummer, of Denver, reported on eighty-seven soldiers who had acute gonorrhea and were treated with fevers of 106.6° to 107° F. for five-hour periods every third day. The patients were divided into treated and control groups. The percentage of cure was the same (72.7 per cent) in both groups but the patients who were treated with fever showed no residual symptoms and the results were accomplished in a third of the time required in the control group.

Trautmen, Stroupe and Devlin, of New Orleans, reported on the treatment of 278 men suffering from gonorrhea. Eighty-seven per cent of the men who had acute gonorrheal infections and 70.5 per cent of those who had chronic infections "were apparently free of gonococcic infection after completion of fever therapy."

Schnabel and Fetter, of Philadelphia, reported on the treatment of 136 patients with gonococcal infections. Seventy of the patients had acute gonorrheal arthritis and twenty had chronic gonorrheal arthritis. Forty-eight of those who had acute gonorrheal arthritis were cured and the remaining twenty-two were improved. Six of those who had chronic gonorrheal arthritis were cured and the other seventeen were unimproved.

Freund and Anderson, of Detroit, reported recovery in a case of gonorrheal endocarditis, following administration of artificial fever at 106.4° F. for thirty hours divided into five periods.

Hazel and Snow, of New York, reported on the successful treatment in one case of gonorrheal septicemia in which two treatments of five hours each at a temperature of 106° to 107.8° F. were used.

TRENDS IN MODERN PEDIATRICS*

F. C. RODDA, M.D.
Minneapolis, Minnesota

ALL successful business concerns find it necessary, at times, to take stock of supply, demand and obsolescence. It is quite as logical for doctors occasionally to evaluate medical practices. With such an appraisal, one is impressed with some very striking changes in the medical care of infants and children. Some diseases have almost disappeared, certain procedures are now obsolete, while our services are needed in new fields.

With such a survey one notes:

1. The practical disappearance of his chief "stock in trade" of thirty years ago, namely, smallpox, typhoid, diphtheria, fatal diarrheas, florid rickets and scurvy.

2. Infant feeding has been reduced to such simple routine that little medical supervision is now necessary.

3. The knowledge of hygiene of heating, ventilation, clothing and contagion has cut down the incidence of upper respiratory infections. A general practice of putting a child with an incipient cold to bed in an equable temperature, forcing fluids and providing a light diet, has cut off many grave complications, formerly necessitating medical attendance.

Now, all of these changes have been to the advantage of the infant and child but result in a sharp economic loss in pediatric practice.

However, to replace these losses, there are newly developing fields of endeavor wherein the child can be greatly benefited and the pediatrician may demonstrate he is still a useful citizen in his community. We are cognizant of much important research in cellular chemistry, studies on glands of internal secretion, chemotherapy, search for new curative and preventive sera and inoculations, as yet not practicable, but we are in possession of other facts, which permit of generalization and daily application. Of numerous advances, there are four which I wish to discuss briefly: (1) preventive medicine; (2) better knowledge of nutrition and growth; (3) promotion of health habits; and (4) prevention and early correction of behavior problems.

*Read before the annual meeting of the Minnesota State Medical Association, Saint Paul, Minnesota, May 3, 1937.

Preventive Medicine

Now, all four of these problems are preventive measures, but I refer especially to the avoidance of certain specific infections. You know successful vaccination will prevent smallpox. Through immunization against it, diphtheria is on the way out. Employment of the Dick technic against scarlet fever or some modification of it, may win general acceptance. Experience with Sauer's vaccine in preventing whooping cough is encouraging and certainly worth a trial. Military experience, throughout the world, testifies to the efficiency of typhoid vaccine against typhoid fever. But wistful wishing will not prevent these diseases. Procedures of active immunization must be carried out. They present no technical difficulties. A reasonable routine would be to begin protection against smallpox, diphtheria and pertussis at about six months of age, or even earlier; against scarlet fever before entering school, and against typhoid in the face of any threatened outbreak and for our transient, widely traveled, trailer population. One might ask how willing are parents to accept this regime? From my own experience I would say they are most cooperative. It is routine with us, well up to 100 per cent, and, moreover, parents are willing to pay reasonable fees for this work.

Growth and Nutrition

Workable standards of growth and development are in our possession; our knowledge of nutrition is increasing; most of the fundamentals are known. Mineral metabolism is on a scientific basis; the necessary amino-acids and their protein sources are known; knowledge of the metabolism of starches and fats, though not final, is serviceable; the chemical structures of four important vitamins are known, three of which can be synthesized. All this knowledge now replaces much which was theory and conjecture twenty-five years ago. But you say it is all so technical. This is not so. Height and weight

determinations compared with standard tables at once inform us of the deviation from the norm. Of course, we can not standardize the human family, and reasonable allowance must be made for familial tendencies and types of body build. An inspection of bone development and the state of dentition gives us information as to skeletal nutrition. A simple blood examination will determine if anemia is present. With a knowledge of the normal, which we should have if we attempt anything in medicine, we now try to correct deviations from the normal in our patients. By referring to memory or simple tables, we can approximate the nutritional demands of our patients and proceed to outline a diet. It is not well known that the science of diet has been reduced to a simple, practical basis. Any recent text on diet will present understandable tables from which a sensible diet can easily be compiled. Too much detail may lead to confusion. In a gross way, one may state the minimal daily diet for a healthy growing child should include:

One and one-half pints of milk.
A generous supply of vegetables.
A generous supply of fruits and fruit juices, especially orange or tomato.
An egg or two.
A moderate amount of meat.
A moderate amount of cereal and breadstuffs.
Water to maintain balance.
Cod liver oil or its equivalent.

A simple anemia will respond to an iron salt. Only a prolonged deficiency diet will require other specific vitamin therapy. Experience and familiarity breed speed and efficiency so that nutritional management can become a pleasant task rather than a bugbear.

Promotion of Good Health Habits

It will be accepted as axiomatic that the health, accomplishments and happiness of an individual depend greatly on habits established in infancy and childhood. In spite of this, they are sadly neglected. By health habits, we mean regular schedules for eating, for bodily evacuations, regular times for play, rest and sleep, bodily cleanliness, care of the teeth, training in obedience and coöperation, social adjustments and numerous other details of living. It is of little value to outline a proper diet if the child will not take it. Undue fatigue may set up a whole train of bad habits, leading to serious problems. An unenlightened mother, in spite of best intentions, may wreck her child's health. Yet, too often, health habits are ignored by the physicians, and the layman often feels that these problems are aside from medicine. From intensive child study, it has been determined how much play, rest and sleep the average child, at a given age, requires. Contributions have also been made in methods of overcoming many problems in child training. All this, again, has been reduced to a practical basis. This, most assuredly, falls within the province of the physician, who should be in position to add just the right amount of common sense necessary to all rules as applied to children.

Behavior Problems

Behavior problems grow out of heredity, faulty health habits and environment. A goodly share of my energy goes into helping parents with behavior problems. I admit many shortcomings on my part, but not a lack of interest. Life is strenuous even for the young. They encounter strains and cross currents quite as much, or more, than the adult. The population of institutions for mentally unbalanced and insane far outruns the capacity to care for them, and the rate is increasing. Students of this situation contend that efforts to correct behavior problems and reduce maladjustments early in life may forestall many of these calamities. Is it strange that Johnny, who is underweight, has severe dental caries, has poor muscle tone, is chronically fatigued, unable to keep pace with his pals, should fall into a whiny, introspective state and become a problem in his home, school and community? Is it strange that Mary, as she approaches puberty and acquires a stepfather, lacking in understanding, should assume the attitude of a rejected child and become delinquent? Who should be in a better position to get a right perspective than the physician who probably brought them into the world and has followed them through their physical tribulations since? Many lesser behavior problems arise which may grow into big ones and eventuate in grave maladjustments. Some of these are thumb sucking, nail biting, head banging, night terrors, temper tantrums, neurotic vomiting and enuresis. These may not be explained away as being caused by teething or worms. A better approach, and one

too often overlooked, is that the patient possesses a psyche which is responding peculiarly to environmental influences. A rational technic is now at our disposal in helping to correct most of these problems.

Now, most of these advances or lead lights have originated in medicine, some from clinical studies and some from tedious research. It is an interesting observation, that when facts have been established and brought to practical application, some bureaucratic agency or uplift organization appropriates the knowledge and at once sets itself up as a fountain head of all truth. But the doctor can do the job much better. We should not let others usurp our rightful place.

When I began my practice only certain activities of a doctor commanded a fee, such as setting a broken bone, administration of an anesthetic, the writing of a prescription and especially cutting or sewing. Time spent on examination or in giving advice was gratuitous. But here, too, I am sure there has been a change in the layman's viewpoint. Time spent in investigating a patient to arrive at a diagnosis and in giving advice, even without medicine or surgery, is now considered worthy of its hire.

I wish, however, to make a still more practical application of this discussion. We hear much of the oncoming state or social medicine. Mark Twain said, "Everybody talks about the weather but no one does anything about it." So it is with state medicine. True, we discuss it in our medical meetings, appoint committees, etc., but we do little intrinsically to avert or lighten the blow. Remember the appeal of the crippled child is universal and provocative. Medical neglect of children provides the most powerful argument for some form of social medicine. Let us look close to home. Some day a survey of your village or county will be made, with the startling disclosure that, for instance, only 5 per cent of the children of school age have been vaccinated against smallpox and perhaps only 3 to 5 per cent against diphtheria. Suddenly some public health organization will come in and clean up this situation. Or again, a survey will show a large percentage of children under weight, anemic, with dental caries and below normal standards. Someone will move in a diet kitchen and tell your countryside how to feed kids. Or again, an uplift association will get excited about some new idea for training in child health habits and, behold, a shepherdess to lead them. Or again, child delinquency will force the setting up of a psychiatric clinic.

It is my contention that the medical profession has the knowledge and equipment to care for these problems, but we must show interest and do something about them. Of course, we need state medicine in an economic sense. There should be monetary help so that indigent parents may avail themselves of these aids and protections for their children, and to provide the laborer a living wage. But we do not need a bureaucratic treatment machine to run over the family physician, or reduce him to a clerkship. The choice may lie with us.

SINUSITIS*

K. R. FAWCETT, M.D.
Duluth, Minnesota

THERE is probably no diagnosis which arouses more suspicion in the mind of the average lay person than that of sinus disease. Time after time the patient confronted with such a diagnosis slides out of the examining chair with the remark that he doesn't wish anything done about it because one of his friends who started treatments for sinus trouble never did get through.

This distrust on the part of the public can mean only one thing. Something has been wrong, and perhaps still is wrong, with our concept of sinus disease. It is upon this premise that this paper has been prepared. The subject can be discussed only in general terms. The time is too short and the audience too general for detailed classifications and exhaustive discussions of the individual sinuses.

Sinusitis, in the not too dim and distant past, has been held responsible for most of the ills

*From the Duluth Clinic, Duluth, Minnesota. Read before the annual meeting of the Minnesota State Medical Association, St. Paul Minnesota, May 3, 1937.

that flesh is heir to. It was eagerly pounced upon as another focus of infection when doctors found out, somewhat to their chagrin, that extracting the patient's teeth and tonsils quite often failed to cure his rheumatism, peptic ulcer, asthma, or kidney trouble. We must admit that hundreds and probably thousands of sinuses have been operated upon ill advisedly. May I quote one example: In 225 cases of retrobulbar neuritis seen at the Mayo Clinic, Benedict[1] reported only one as due to sinus disease. Yet among 500 cases of multiple sclerosis, 60 per cent or 300 patients had had intranasal sinus operations because of visual disturbances—one of the common early symptoms of multiple sclerosis. A similar picture, nearly as bleak, could be painted for sinus surgery directed toward the cure of asthma. It is for reasons such as these that the subject of sinus disease is accompanied by a large question mark in the minds of our patients.

Physiology

The anatomy and physiology of the sinuses may be summed up very briefly. Each sinus has an opening into the nasal cavity, and is ventilated with each respiration, the pressure dropping below normal with inspiration and going above normal with expiration. The interior of the nose and sinuses is lined with ciliated epithelium, and the normal mucous secretions are swept in a steadily moving film by the cilia toward the pharynx and down into the stomach. Thus infective particles that gain entrance to the nose or sinuses are promptly swept out again. Most sinuses are normally sterile.

What then, we may ask, causes sinus disease? The causes may be divided into two groups: local and general. Under local we must consider anything which interferes with the normal ventilation and drainage of the sinuses, such as congenitally narrow nasal passages, adenoids, deviations and spurs of the nasal septum, and enlarged, malformed turbinates. Under general causes we must consider factors which lower our resistance, such as exposure to cold, fatigue, improper food, overheated rooms, and lack of proper humidity. In addition, as regards the maxillary sinus, we must remember that the roots of the upper teeth lie in close proximity, and the records of the Lahey Clinic, as reported by Hoover,[2] show that 10 per cent of antral infections are dental in origin.

Bacteriology

Our knowledge of the bacteriology of sinus disease is, like that of the common cold, not as yet satisfactory. In 166 cases of maxillary sinus disease, acute and chronic, Enlows and Alexander[3] found pure cultures of streptococcus viridans in 43 per cent. The pneumococcus was found alone in 14 per cent. Streptococcus hemolyticus in pure culture was present in 9 per cent, and the remaining third of the cases were made up of various mixtures of streptococci, staphylococci and pneumococci. Interestingly, there were no evidences of micrococcus catarrhalis, and no anerobic organisms. Following the work of Dochez, a filterable virus seems to be pretty definitely established as the primary etiologic agent, but the presence of the virus does not detract from the importance of the accompanying organisms mentioned above which apparently become activated by the virus. It is significant that swine influenza is transferable only by a virus *plus* bacteria.

Symptomatology

Most of the symptoms of sinus disease, such as nasal discharge, local pain, temperature, sensitivity of the upper teeth, et cetera, are too well known to merit discussion. It is my impression that the patient with a chronic cough or bronchitis is occasionally overlooked as a sinus suspect. The symptom complex in children should be reviewed. It consists of chronic cough, anemia, loss of weight, frequent colds, a pasty complexion, nasal discharge, headache, cervical adenitis, and frequent otitis media.

Wherein lies our biggest error in the diagnosis of sinus disease? The question of allergy is approached with considerable trepidation because of its recent popularity in all fields of medicine, and yet there can be no doubt but that allergic states have been the most common cause of incorrect diagnoses of sinus disease. The pallor of the nasal mucous membranes is the first clinical finding that should put us on guard. The family history is all important. The presence of numerous eosinophiles in the smear of the nasal secretion is almost pathognomonic. Do not let the sinus x-ray deceive you. The sinuses

may appear cloudy simply because of allergic thickening of the lining mucous membrane, and the roentgenologist must if possible learn to differentiate between this allergic thickening and actual disease.

Brief mention should be made of the complications of sinus disease. Our greatest danger lies in direct extension to the brain in the form of meningitis, brain abscess, or cavernous sinus thrombosis. Sander[4] reviewed the recent reports in the literature and found that 8 per cent of brain abscesses were due to infected frontal sinuses. Orbital abscesses may develop from ethmoid infection, and at times require external drainage in addition to drainage through the nose. Otitis media, especially in children, has already been mentioned. Ferraris[5] discusses the literature on the subject of optic neuritis and advises conservatism as regards sinus surgery. Iwaszkiewicz[6] analyzed 732 cases of sinus disease and found that only 3 per cent showed ocular complications. Farrell[7] reports 86 per cent of 66 cases of bronchiectasis showing roentgen evidence of sinus disease. The question of asthma needs careful analysis. Cooke and Grove[8] studied 248 cases of asthma due to bacterial allergens and found the sinuses to be the etiologic factor in 92 per cent. One hundred and twenty of these patients had radical sinus surgery, and 70 per cent of these were definitely improved. Sinus surgery is *not* indicated in asthmatics whose allergen is *not* bacterial.

Treatment

The treatment of sinus disease can be discussed but briefly. We should consider carefully the question of prophylaxis. In children it is generally accepted that the removal of diseased tonsils and obstructing adenoids is the most effective therapeutic measure. In adults, submucous resection to open up noses blocked by deviations and spurs of the septum is definitely indicated. The study of questionnaires sent to our patients following submucous resection reveals a rather marked diminution in the number of winter colds and sinus complications. General hygiene, including proper diet, rest, ventilation, and humidity can be only mentioned. Large doses of vitamines A and D have *not* decreased the incidence of respiratory infections in children. Vaccines have been used for many years, but it is the concensus of opinion that most mixed vaccines confer a minimum of protection.

Acute sinusitis should be treated, as a rule, conservatively. Our purpose should be to aid the normal physiologic activity of the nasal membranes. Proetz says, "To my mind the cilia are by far the most potent factor in restoring and maintaining nasal health."

The medicinal agents used in the treatment of sinusitis are too varied to admit of any specificity. Parkinson[9] states, "By no interpretation of physiologic facts can one correlate such different substances as oils, colloids, antiseptics, lysates, electrolytes, adrenalin, cocaine, ephedrin, and their innumerable combinations." A review of the physiologic action of various commonly used nasal medications is extremely illuminating:

Liquid petrolatum, the vehicle of most of the nose drops on the market, causes marked slowing of the ciliary stream.

Argyrol and neosilvol cause a similar slowing.

Adrenalin 1-1000 causes immediate ciliary paralysis.

Cocaine in more than 2.5 per cent concentration causes slowing or paralysis of the cilia.

Merthiolate even in 1-10,000 dilution causes slowing.

Eucalyptol, menthol, thymol, zinc sulfate, and adrenalin all definitely slow or paralyze the cilia.

Tap and distilled water promptly stop all ciliary activity.

Physiologic saline has no effect on the cilia.

Ephedrin from 0.5 to 3 per cent in saline is harmless and may even cause sustained acceleration.

Thus, the only drug for which we have a physiologic indication in the nose is ephedrin, dissolved preferably in normal saline.

Local heat, in the form of moist packs or the infra red lamp, is definitely efficacious. Steam inhalations are helpful in that they render the muco-pus more liquid, making it easier for the cilia to clear the nasal passages.

Operative procedures in acute sinusitis are necessary only when pain and fever indicate

obstruction of drainage and should be limited to the evacuation of the pus. Lillie[10] calls attention to the bad effects of frequent, prolonged irrigations of the nose and sinuses because of their tendency to waterlog the mucous membranes.

Chronic sinusitis can often be prevented by recognition and proper treatment of the acute case. In considering surgery we must be governed largely by the condition of the sinuses themselves. The persistence of chronic infection, thickened, hyperplastic mucosa, and polyps call for surgical interference, and the choice between intranasal and radical procedures must depend on the degree and extent of the involvement.

Conclusions

In conclusion, may I emphasize two points:

1. Allergy must always be considered as a primary factor in nasal disturbances, and must be carefully ruled out before a diagnosis of sinusitis is made.

2. We must be much more conservative in advising sinus surgery, particularly to patients with asthma or ocular symptoms, if we are to win back the confidence of the general public regarding the treatment of sinus disease.

CONVALESCENT SERUM TREATMENT IN THE PREPARALYTIC STAGE OF POLIOMYELITIS

BURTON ROSENHOLTZ, M.D.

Saint Paul, Minnesota

THIS study of 2,761 clinical and 1,855 control cases was made with the idea of determining statistically the specificity of human convalescent serum in the treatment in the preparalytic stage of anterior poliomyelitis. Such an evaluation is difficult for various reasons. The material comes from different localities and over a period of years and epidemics, of course, vary greatly as to locale and time. The methods of handling material are not standardized. What one observer calls paralysis, another calls a paresis or muscle weakness. In some cases we have definite follow-up observation, and in others none. One of the greatest difficulties comes from the lack of large numbers of scientifically adequate controls. For this study, however, we felt that certain prerequisites were necessary. First, only those cases were included in which the diagnosis, we felt, was unimpeachable. That is, diagnosis depended on spinal fluid counts plus the symptomatology and the course of the disease. Second, only those cases which were treated in the preparalytic stage are included in this study.

The main considerations in determining the specificity of convalescent serum are three in number: (1) mortality; (2) the amount of paralysis or muscle weakness during the acute stage; and (3) the residual paralysis.

For the sake of exactness, we have divided the cases into three groups: (1) those with no control; (2) those with controls which we felt for one reason or another were not to be relied on as scientifically accurate, and (3) those with controls scientifically sound.

Table I shows the evidence derived from the uncontrolled material. It is interesting to note the extreme differences in results in both the mortality and paralysis or muscle weakness. In this group of 215 cases all treated with human convalescent serum we have an average mortality of 9.4 per cent, paralysis of 8.1 per cent and no residual paralysis in 51.1 per cent.

TABLE I. UNCONTROLLED GROUP

Author	Time	Place	Number Exper. Cases	Number Cases Control	Deaths		Paralysis or Muscle Weakness		Residual No Paralysis	
					Control	Exper.	Control	Exper.	Control	Exper.

Aycock	1928	Mass.	116	297	18.5%	6.0%	?	61.2%	53.3% About	43.0% 3 mo.
			637	1051	12.0% AV.	3.0% AV.	31.3% AV.	34.1% AV.	49.8% AV.	61.0% AV.

Table II is that of the inadequately controlled group. The controls in most instances in this group were seen after the acute stage, in some cases months after, and the mortality was taken from records. This is not true in the groups of Zingher and Ayer. Zingher's controls include twelve taken from hospital records and ten cases in which horse serum was given. Ayers thirty-one controls were all given pneumococcic serum. In this table, it will be noticed that no figures are available in the last two columns in the groups of Silverman, McEachern and MacNamara, as there was no follow-up recorded in these cases. The finest work in this group was undoubtedly done by Aycock at the Harvard Medical School. The muscle examinations in these patients were done with the idea of arriving at figures to show percentage of paralysis per patient. His controls, however, were all patients seen after the acute stages by the Harvard Committee on Infantile Paralysis. One must, however, be especially careful in comparing the results in a group of treated cases with a group of untreated ones taken at large, for the reason that the number of mild abortive cases missed is indeterminate.

To sum up the evidence, from this group of 637 experimental and 1,051 inadequate control cases we find that the only significant evidence

TABLE III. ADEQUATELY CONTROLLED GROUP

Author	Time	Place	Number Exper. Cases	Number Cases Control	Deaths		Paralysis or Muscle Weakness		Residual No Paralysis	
					Control	Exper.	Control	Exper.	Control	Exper.
Laidlaw	1931	N. Y.	689	45	4.4%	3.5%	24.4%	19.1%	71.1% (3 wks.:	77.4% 3-4 mo.)
Park	1931	N.Y.C.	519	408	.9%	3.8%	28.0% (3-4 w	27.2% eeks)	84.7%	76.6%

Previtali	1931	N.Y.C.	7	20	.0%	.0%	5.0%	3.0%		
Aycock	1931	Mass.	42?	40	.0%	5.0%	56.4%	46.5%	43.6%	53.5%
Fisher	1931	N.Y.C.	477	102	2.0%	3.8%	27.4%	27.2%	84.7% (6	78.6% Mo.)
Dennig	1932	Stettin, Germany	7	8	.0%	.0%	13.0%	15.0%	87.0%	84.0%
			1709	804	3.03% AV.	2.6% AV.	42.7% AV.	22.6% AV.	73.0% AV.	74.9% AV.

for the specificity of convalescent serum is to be found in the average mortality. Here we find that there is a 3 per cent mortality in the experimental group as against a 12 per cent mortality in the controls. This, statistically, is a really significant difference. The 34.1 per cent paralysis in the treated and 31.3 per cent in the controls is a difference which is insignificant. As also is the 11 per cent difference in favor of the treated group in the residual.

The next table is the most important, for it is the one in which all controls are adequate and scientific.

It is Park's organization which has made the first three groups possible. Before the epidemic of 1931 the Health Department of New York City was well organized so as to record a large number of bona-fide, unselected controls, seen by physicians of the Academy of Medicine under Park's supervision. Park, realizing that most patients treated at home requested serum, stopped using it on the patients treated at the hospitals. In this group of a rather large number of treated and control cases, there is, as can be seen, no significant statistical difference between the two, except in the mortality, where four times as many patients died among those treated as in the unselected scientific controls.

Laidlaw's material, which came from upper New York State, was gathered in much the same way as Park's, consultants seeing all cases reported from the beginning.

Previtali's first group comes also from Park's organization. The 181 controls marked B and C were given, in some cases, horse serum, and in others, no serum. A is the group treated with human convalescent serum. The differences in each column, between these three groups, are definitely, statistically insignificant with the possible exception of the mortality, which is lower in those untreated than in those in which convalescent serum was used. The next group of Previtali is from his own private practice.

Aycock's group, although smaller than some of the other groups, has been very thoroughly studied. His controls are also unimpeachable, each patient having been studied from the standpoint of per cent paralysis per patient. Again, we find in this most intensive study a significant difference only in the mortality, and that definitely in favor of the controls. At this point it is of interest to note that Aycock's conclusion after the epidemic of 1927 in which inadequate controls were used was most optimistic, whereas he concluded from the work of 1931, using adequate controls, that he "failed to obtain statistical evidence that convalescent serum is effective."

No large well controlled group treated only in the preparalytic stage has been reported since 1932.

The averages in Group 3 or that of adequate controls have not been commented upon before. The lack of significant difference in this, the most important group, is obvious, in all columns

TABLE IV

	Mortality		Paresis		Residual No Paralysis	
	Control	Exper.	Control	Exper.	Control	Exper.
Group 1. No Controls		9.4%		8.1%		51.1%
Group 2. Inadequate Controls	12.0%	3.0%	31.3%	34.1%	49.8%	61.0%
Group 3. Adequate Controls	3.03%	2.6%	42.7%	22.6%	73.0%	74.9%

except that having to do with paralysis, where the treated cases showed an average 22.6 per cent and the control cases 42.7 per cent. However, this difference is not one of statistical significance (Table III).

Table IV shows the averages already given. The group of inadequate controls shows, as we have said, no significant statistical difference except in the mortality, and that is in favor of the treated group.

Conclusion

From this statistical study, especially of the group in which we had 1,709 treated cases and 804 adequate controls, there is no evidence that human convalescent serum is of value, when used in the preparalytic stage of anterior poliomyelitis.

No Sunshine in Soap

During the past year certain brands of soap have been flamboyantly exploited for their vitamin D content; one for the "filtered sunshine" in its lather. The latter product was introduced to the public with double page spreads in national magazines under the caption: "The Dawn of a Great Beauty Discovery." There is evidence that irradiated ergosterol may be absorbed through the skin of rats. This evidence has been an excuse for adding vitamins to various cosmetic preparations. Redgrove points out that the real question at issue is not the ability of the skin to absorb these substances, but "whether when so absorbed the vitamins exercise any beneficial action on the skin—in short, whether they are of any cosmetic value." Even if it is established that vitamin D exercises any beneficial action on the skin, it still must be proved that it has a beautifying effect. As a matter of fact, there has been some recent evidence which indicates that the alleged beneficial effects mentioned by Redgrove as resulting from the use of cod liver oil in the promotion of healing of wounds and burns were probably due to some other factor than the vitamin D content of the oil. It is not surprising that the Federal Trade Commission has recently published a complaint issued against a manufacturer who has made extraordinary claims about his product. The advertiser who proclaimed the Dawn of a Great Beauty Discovery may soon be worrying about the twilight of the day when the sky was the limit for claims about "sunshine soaps." (Jour. A.M.A., August 14, 1937, p. 509.)

CASE REPORT

MALIGNANT HYPERTENSION FOLLOWING BILATERAL LUMBAR SYMPATHECTOMY FOR RAYNAUD'S DISEASE*

BAYARD T. HORTON, M.D., and HAROLD J. BRUMM, M.D.

Rochester, Minnesota

Raynaud's disease and malignant hypertension both are encountered somewhat infrequently in general practice. This case is reported because, as far as we know, it is the first of its kind. Both diseases are characterized by occurrence of vasospasm. Furthermore, surgical treatment of Raynaud's disease of the lower extremities and of essential hypertension is very much alike, consisting in the former case, of performing lumbar sympathetic ganglionectomy and a resection of the sympathetic trunk and, in the latter case, consisting of performance of a more extensive sympathectomy of the Adson-Craig type. In the case reported below, hypertension of the malignant type developed in spite of performance of bilateral lumbar sympathetic ganglionectomy and a resection of the sympathetic trunk for relief of Raynaud's disease.

Report of Case

A white, married woman, aged forty-five years, came to The Mayo Clinic for the first time on April 1, 1932. She complained of color changes of the fingers and of the hands on exposure to cold. Her first symptoms began in May, 1931, when she noticed blanching of the little finger of the left hand; this was promptly followed by symmetrical involvement of all the digits of both hands. The red, white and blue color phases were noted. Pain was not experienced with these early color changes. Similar color changes were noted simultaneously in all the toes in January, 1932.

Excitement and exposure to cold always brought on her symptoms. Later, these symptoms were accompanied by numbness of the digits and by generalized weakness. She promptly recovered from her symptoms in a warm room. This patient also stated that occasionally a tired feeling developed in the calf muscles of both legs when walking on a cold day. On two occasions she had to stop walking. Rest gave prompt relief. She had also experienced similar sensations while dancing. She had observed that she could walk farther on a warm day than she could on a cold day. This patient's father and mother were living and were well. Four sisters were alive and were well. Two brothers were considered to be well until they were six years of age at which time both of them developed an insidious paralysis of the legs and became invalids; one brother died at twelve years of age and the other died at nineteen years of age. There was no history of hypertension in the family. The patient had been married fifteen years and had two healthy children. Her menstrual periods were normal, but flow was scant.

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

At the time of her physical examination the fingers and toes were cold, mottled and cyanotic. Pulsations in the brachial, radial and ulnar arteries, as well as in the femoral, popliteal, dorsalis pedis and posterior tibial arteries were within the normal range. Definite scleroderma was not present. Neurologic examination gave objectively negative results. In a room of which the temperature was 23.8° C., the surface temperature of her fingers ranged from 25.5° C. to 26.1° C., and the surface temperature of her toes ranged from 26.1° C. to 28.1° C. Following oral administration of 1 ounce (30 c.c.) of ethyl alcohol, there was a uniform rise of the surface temperature of her fingers of 10° C. to 10.6° C. The rise of surface temperature of her toes was somewhat less uniform and ranged from 6.9° C. to 10.2° C. Normally, the surface temperature of the feet rises less than that of the hands during this test.

The blood pressure was 132 mm. of mercury systolic and 84 diastolic: the pulse rate was 96 per minute. Examination of the ocular fundi by Dr. Wagener revealed some excess glial tissue on the disks. The retinal arteries had an exaggerated reflex but sclerosis was not present. The specific gravity of the urine was 1.030; the urine was acid in reaction and albumin and sugar were not present; microscopic examination gave negative findings. The concentration of hemoglobin was 14.2 gm. per cent, erythrocytes numbered 4,450,000 and leukocytes numbered 5,700 per cubic millimeter of blood. The serologic test for syphilis and a roentgenogram of the chest gave negative results. Special examination of the urine for lead and arsenic showed that lead was not present, but 200 c.c. of urine contained 1.03 mg. of arsenic.

On April 8, 1932, Dr. Craig performed a right and left lumbar sympathetic ganglionectomy and a resection of the sympathetic trunk for the Raynaud's disease. The patient had an uneventful recovery and the wound healed by primary intention. The feet were warm, pink and dry at the time of her dismissal. No changes were noted in the hands.

On July 23, 1937, the patient returned to the clinic complaining of blurred vision, of headaches during the past two months and of hypertension for one year. In March, 1934, her blood pressure was 145 mm. of mercury systolic and 90 diastolic.

In July, 1936, her family physician found that she had a severe degree of hypertension. Headaches were severe, but administration of acetylsalicylic acid (aspirin) gave her relief to a slight extent. Her vision had diminished so that it was difficult for her to distinguish people at a distance of 10 feet (3.3 meters).

Approximately four years previously, the skin of the terminal phalanges of the hands and the skin about her mouth, face and neck had become tighter and definite evidence of scleroderma had developed. She had continued to have color changes of the Raynaud type, in the hands but not in the feet.

Physical examination revealed a thin, emaciated woman who had a glossy, tightened skin over the face, neck and terminal phalanges of the hands. No scleroderma was present in the feet; she weighed 87 pounds (39.5 kg.). The blood pressure was 234 mm. of mercury systolic and 150 diastolic. When the blood pressure was taken at hourly intervals, there was a systolic range of 190 to 240 mm. of mercury and a diastolic range of 100 to 170. The second aortic sound was accentuated. Examination of the fundi by Dr. Wagener revealed generalized narrowing of the retinal arteries of grade 1 to 1+ (on a basis of 1 to 4), sclerosis of grade 1 to 2 and localized angiospastic narrowing in the smaller and more peripheral arteries. Scattered cotton wool exudates and hemorrhages were present, as well as edema of the disks to an extent of 2 to 3 diopters. Macular stars were not noted. From the appearance of the ocular fundi, Dr. Wagener thought that one should consider the possibility of acute angiospastic retinitis, in contrast with that of frank malignant hypertension. Pulsations could not be detected by palpation of the ulnar arteries or of the left dorsalis pedis artery. Pulsations were present in the other palpable arteries but seemed markedly reduced in force. No definite sclerosis was evident. The surface temperature of the fingers was approximately 27.5° C. and the surface temperature of the toes was approximately 26° C. with the patient in a room of which the temperature was 77° F. (25° C.) and the humidity was 40 per cent. It is interesting to note that the surface temperature of the digits was essentially the same at the time of her second admission to the clinic as it was during her first visit.

Urinalysis revealed albumin grade 2 to 3 on a basis of 1 to 4; the specific gravity was 1.015 to 1.019; microscopic examination gave negative results. The concentration of blood urea and of blood sulphates was 30 mg. and 3.5 mg. per 100 c.c. of blood, respectively. The concentration of hemoglobin was 15.2 gm. per cent; erythrocytes numbered 4,040,000 and leukocytes 5,800 per cubic millimeter of blood. The basal metabolic rate was +32 per cent. A roentgenogram of the thorax gave evidence of cardiac enlargement and of dilatation of the arch of the aorta. The electrocardiographic tracing revealed a cardiac rate of 119 per minute, sinus tachycardia, iso-electric T waves in derivation 3 and QRS complexes that were notched in derivations 2 and 3 and slurred in derivation 1. The serology of the blood was normal. Following intravenous administration of pentothal sodium (565 mg.) the blood pressure decreased from 200 systolic and 135 diastolic to 180 systolic and 124 diastolic. With administration of 9 grains (0.6 gm.) of sodium amytal, the blood pressures dropped from 220 and 160 to 168 and 112. Following administration of 3 grains (0.2 gm.) of sodium nitrite, the blood pressure decreased from 198 and 140 to 180 and 126. It is very obvious from these tests that the patient had a fixed type of hypertension and she was not suitable for performance of extensive sympathectomy such as has been carried out at the clinic by Drs. Adson and Craig. She died about three weeks after leaving the clinic.

Comment

It seems logical to assume that the vasospastic disturbance which was originally present in the hands and feet and which did not give rise to hypertension had finally become generalized and was of such degree that it produced a severe hypertension which explained the final clinical picture. In our experience, in the average case of Raynaud's disease, a normal or a subnormal blood pressure is present.

Development of scleroderma in the hands, face and neck was fairly marked at the time of her second visit but there was no evidence of the presence of scleroderma in the feet. Apparently the operation of sympathectomy for the condition in the lower extremities had prevented development of scleroderma in the feet.

At the time of the patient's first admission to the clinic, she presented all the classical signs and symptoms of Raynaud's disease and yet complained of definite intermittent claudication in the lower extremities. This is the first time we have observed this symptom in a case of Raynaud's disease. In fact, we were previously inclined to think that this symptom did not occur in Raynaud's disease.

The finding of arsenic in the urine was apparently accounted for by the fact that previously she had been taking Fowler's solution.

Even though the basal metabolic rate was +32 per cent there was no other evidence of hyperthyroidism. It is not uncommon, in our experience, to observe metabolic rates of this height in cases of severe malignant hypertension.

It is extremely interesting to note that pulsations in the ulnar arteries as well as in the left dorsalis pedis artery could not be detected at the time of her second admission to the clinic, although these arteries pulsated normally at the time of her first admission. It is most unusual to observe occlusion of peripheral arteries of this caliber in cases of essential hypertension and we have not observed it in cases of frank Raynaud's disease. We cannot give an adequate explanation of this phenomenon.

Antitularemic Serum-Mulford

Sharp & Dohme, Inc., presented for the consideration of the Council on Pharmacy and Chemistry Antitularemic Serum-Mulford prepared by immunizing horses by injecting cultures of B. tularense isolated from human cases of tularemia. On request of the Council, Dr. Lee Foshay of the College of Medicine, University of Cincinnati, kindly submitted comparative data obtained from 334 untreated cases of tularemia and 481 serum treated patients. He gave a separate analysis of 133 patients (included in the treated group) who received Antitularemic Serum on or before the twelfth day of the disease. The Council considered Dr. Foshay's data, and, while finding nothing definitely to criticize, concluded that corroborative data by other investigators are needed before the product can be accepted for inclusion in New and Nonofficial Remedies. The Council therefore voted to postpone consideration of Antitularemic Serum-Mulford (Sharp & Dohme, Inc.) to await development of further data. (Jour. A.M.A., August 14, 1937, p. 504.)

THE BACKGROUND OF MEDICAL HISTORY FOR NORTHEASTERN MINNESOTA AND THE LAKE SUPERIOR REGION

By RICHARD BARDON, M.D.

A SUMMATION of some of the medical and hospital history of northeastern Minnesota and the region of Lake Superior merits a brief introduction outlining three major epochs. While the present review is not primarily intended to cover the early exploration period of the eighteenth century, the reader will be better oriented by a short reference to this early colorful period. Two relatively recent books, "The Voyageurs," by Grace Lee Nute, and "Early Candle Light," by Lovelace, should be read by all those seeking a background for our present-day commonwealth.

This early period was decidedly French, or rather, French-Canadian, Indian, and ultimately English as they became supreme in the New World. The human side of the transfer of a great wilderness from Indian control to white usurpation is largely a story of the colorful "Voyageurs de Bois." They were the trekkers, the "safari" for the great fur trading companies in a day when transportation was a matter of canoes, portages, fur trading stations or forts for traffic with the Indians. The voyageur was in the beginning scarcely a generation removed from the immigrant—the most spirited and virile of the French when their nation was in the "Golden Age of Louis the Grand." They were sprightly, singing, praying, cursing, incorrigible, adaptable, indefatigable, and left a heritage and an imprint on this region which may not readily be effaced. Fur trading was not so much a means of gaining a livelihood as an excuse to live in a manner so peculiarly adapted to their temperament and physique. It is too easy in retrospect to lose a sense of their moral fiber and religious devotion in the livelier tales of their drinking, carousing and direct eugenic alliance with the natives. They learned from the aborigines the "methods of living off the country"; in return, they left indelible geographic landmarks and racial imprints: the names of cities, capes, promontories, lakes—mostly French translations of old Indian names. As with all primitive contacts, industrial and missionary in character, the doctors and priests, with the Indian medicine men, became something of a blur. The ability to offer healing solace to the sick or injured was the best approach to the matter of weaning a wavering soul away from pagan worship. The doctors who accompanied the fur traders were, for the most part, itinerants, if not adventurers.

The second phase or epoch began when wars among the European peoples ceased for a full century to embroil their compatriots in the New World. The industrial development of this north region came after the enormous agricultural growth in the mid-American continent, when its fertile land, as James J. Hill said, "had the Indian taken out of it." The varied national groups soon demanded lumber in large amounts. The settlers were readily adapted to the land; they had an extraordinary urge for independent thinking and extreme self reliance. They brought their wives and children, and came to remain; to build cities and farms;

to develop direct land transportation, such as railroads, in contrast to laborious seasonal canoeing via circuitous water routes and portages. The demand for lumber inspired an onslaught of unheard-of proportions, and within four decades the great timber belts of Michigan, Wisconsin and Minnesota yielded, to the axemen and the mills, their centuries of growth. The lumbermen came largely from Maine and Canada, and occupied the timber states—Michigan, Wisconsin and Minnesota—in sequence. In comparatively recent years, after denuding much of Minnesota, they made broader jumps to the far south on the one hand and the Pacific Coast on the other. Scarcely, however, was the timber cut off when iron ore was discovered in large amounts, and offered another inspiring field for industrial exploitation. It had its ægis in the corresponding demand of an era of city and industrial expansion, and was comparable to the agricultural stimulus that speeded up the lumber mills. In any case, industrialism gave the permanent establishment of most of our hospitals that came later. No longer were the doctors itinerants, and a considerable portion of our narrative will deal with the vigorous pioneers who, coming with the above industries, took on, more or less, both the attributes of the times and the atmosphere of their associated industries.

It was not until 1871 that a railroad came from the South (the Northern Pacific, or, as it was known then, the St. Paul and Duluth Line). Up to that time the contacts, medical and otherwise, were far more with the lower lake ports, via water transportation, and to a lesser degree by rail and stage connections with St. Paul. Up until the '90's the medical practitioners came for the most part from eastern Canada, the New England States, or had followed the lumber industry from Michigan up through Wisconsin. Only after 1900 did more and more graduates from our own medical schools settle in northeastern Minnesota.

The early medical history of St. Louis County naturally is the history of the City of Duluth itself, and consequently we shall attempt to sketch the types of hospitals and methods of support devised in the development of the lumber and mining industries. St. Mary's Hospital in Duluth, for example, sold tickets to the men in the lumber industry covering the cost of their hospital and medical care should they be sick or injured. The price of the tickets varied somewhat, but was in the neighborhood of $12 per year, and served a definite purpose in giving the lumberjacks proper medical care and at the same time developing the early hospitals of our city and county. It was something of an outgrowth of this method that led to the development of most of the iron mining hospitals, except that the assessments were levied monthly, depending on the employment. The plan, under various modifications, still exists.

No historical period abruptly ends when another begins; it is so with our empirical and arbitrary divisions given in this introduction.

The third phase of medical and hospital development took form about 1910. There were no obvious changes in the type of management, for example, of the two large hospitals (St. Mary's and St. Luke's) in Duluth, but with the gradual development of agriculture in northern Minnesota and with urban growth commensurate with wider diversification there came the same change in the type of our hospitals characteristic of all in our state. It may suffice to mention that this change coincided with the period in which rampant epidemics, such as typhoid, ceased to recur, and specialism in medicine developed. The profession adapted itself to the gradual division of its labors, and hospitals were built for the expanding needs. This, very shortly, had its influence upon the hospitals: they became very much more complex units, with a service expanding as rapidly

in unit cost as in efficiency. They have become, in other words, symbolic of our eager, alert and vigorous times.

* * *

The Era of Exploration and Fur Trading

A knowledge of the early medical history of northern Minnesota depends on the records left by the fur traders and the reports of the government expeditions into this part of Minnesota over one hundred years ago. The Northwest Fur Company, in particular, had men in its employ who were physicians, but who were primarily traders, or what were known as "clerks." They kept diaries and made reports to their superiors in Montreal, and it is from these records that we have information as to conditions then existing. The records of the various government expeditions that traveled through our part of Minnesota are of twofold interest in that they usually contain reports of the surgeon of the party pertaining to medical matters, as well as other interesting episodes of early travel in the Northwest. It is from these sources that the following information was obtained:

About the year 1750[7] a war party of more than a hundred young men of the Fond du Lac band of Indians visited Montreal to assist the French in their war with the British. They became infected with smallpox, and but few of the party survived to reach their home. It does not appear, although they made a precipitous retreat to their own country, that the disease was at this time communicated to any others of the tribe.

About the year 1782 smallpox again appeared among the Chippewas of Lake Superior. The circumstances connected with this introduction are interesting. Sometime in the summer of 1781 a trader who had ascended the Mississippi and established himself near Leech Lake was robbed of his goods by the Indians residing at that lake, and in consequence of his exertions in defending his property he died soon after. It is of non-medical interest to note here that even to this date the band of Indians living in the region of Leech Lake are known as the "pillager" band of Indians. The facts concerning the death of the trader became known to the British at Mackinac and requests were sent to the Leech Lake Indians that they should visit Mackinac and make reparation for the goods they had taken. At the same time, they were threatened with punishment in case of refusal to do so.

In the spring of 1782[9] the Indians decided to comply with this request, and a deputation from the band visited Mackinac with a quantity of furs which they considered an equivalent of the goods which had been taken. The delegation was received with politeness by the English and the difficulties were readily adjusted. When this was effected, a cask of liquor and a British flag, closely rolled, were presented to the Indians as a token of friendship. They were at the same time strictly enjoined neither to break the seal of the cask nor to unroll the flag until they had reached the heart of their own country. These directions they promised to observe, but on reaching Fond du Lac, Superior, after many days' travel, they could not resist temptation, and unsealed the cask and unrolled the flag for the gratification of the tribesmen. The Indians drank the liquor and remained in a state of inebriation for several days. The rioting was soon over and they were fast recovering from its effects when several of the party were seized with violent pains. This was attributed to the liquor they had drunk, but the pain increasing they were induced to drink deeper of the liquor, and in this inebriated state several of the party died before the real cause was suspected. Other like cases occurred, and it was not long before one of the party, who had visited Montreal in

1750 and who had narrowly escaped with his life, recognized the disease as the same which had attacked his party at that time. The malady proved to be smallpox, and nearly the whole population of three hundred Indians then at Fond du Lac was wiped out. Although the epidemic did not extend easterly on Lake Superior, it is believed that not a single band of Chippewas north or west of Fond du Lac escaped its ravages. As late as 1832 the Indians were firmly of the opinion that the smallpox had been transmitted by the articles presented to their brothers by the British at Mackinac, as a punishment for their crime against the trader at Leech Lake.

Grand Portage, said to be the oldest permanent white settlement in Minnesota, is located in Cook County, and has a glamorous past, not easily visualized from what remains. There is no actual record of the date when the white men first visited Grand Portage. It is possible that Radisson and Groseilliers were there in 1660, and Du Luth probably in 1679. In 1731, however, Sieur de la Verendrye recorded his visit to Grand Portage. Subsequently the French, and later the English, used Grand Portage as a depot for supplies destined for the fur trade in western Canada, the district north of Lake Superior, and the upper Mississippi region. Jonathan Carver, the associate of the celebrated Major Rogers, arrived at Grand Portage in 1767. The present popular historical novel, "Northwest Passage," mentions such familiar names as the St. Croix and Brule rivers as routes of travel for Carver on his canoe voyage from the Mississippi to Grand Portage. During the Revolution, in 1778, there was on duty at Grand Portage a small detachment of British soldiers, under the command of a Lieut. Thomas Bennett—the sole participation of the present state of Minnesota in the Revolutionary War. With the formation of the Northwest Fur Company in 1783, Grand Portage began an era of activity and importance that continued until about 1801, when the Company moved its headquarters to Fort William. Much has been written about Grand Portage, and an article by Solon J. Buck in the *Minnesota History Bulletin* tells the story well.

The historical background of Grand Portage is of interest to the medical profession of Minnesota because it was here, as an employe of the Northwest Fur Company, that the first physician in what is now Minnesota resided. Dr. Henry Munro[8] was born in 1770, the son of Honorable John Munro, one of the members of the first legislative council of upper Canada. In 1796 he entered the service of the Northwest Fur Company as surgeon, and for several years was stationed at or near Grand Portage, at a salary of "1,200 Grand Portage currency." Dr. Munro apparently acted as both surgeon and trader, and in 1804 or 1805 was sent to succeed J. B. Perrault "at the Pic" on Lake Superior.[2] During the war of 1812, when the Northwest Fur Company raised among its men a corps of Canadian voyageurs to fight the Americans, Dr. Munro was appointed "Surgeon's Mate." This corps, commanded by William McGillivray, a famous "Northwester," served in at least two engagements, and was disbanded at Lachine, near Montreal, on March 14, 1813. It is said that the jovial, carefree voyageur was not temperamentally suited to army life, and apparently the corps was not as successful as anticipated. Dr. Munro died August 20, 1854, at Lachenaie, lower Canada, and is buried in the old Protestant cemetery at Mascouche.

Perhaps the most colorful figure of the early fur traders in this district was Dr. John McLoughlin,[3,4] who was at Grand Portage and Fort William, apparently as an assistant to Dr. Munro. Dr. McLoughlin was an apprentice and student of Dr. James Fisher of Quebec for "four years and 6 mos." (a letter from Dr.

Fisher dated April 30, 1803, certifies to that effect), and he was licensed to practice "Surgery, Pharmacy or Apothecary" on May 3, 1803, and apparently was employed by the Northwest Company shortly thereafter. There is record of his residence at Lake Vermillion (some say it was Crane Lake) during the winter of 1807-08 as a trader and surgeon.

Letters of Dr. McLoughlin written in 1808 and 1810 are interesting, inasmuch as they give some idea of his salary, which was apparently not satisfactory to him. They also, in view of what happened in his later life, are typical of his spirit and outspoken nature.

In a letter from Fort William in 1808 Dr. McLoughlin writes to his uncle:

"You tell me in your letter that they may increase my wages. I think they may as I have been doing Dr. Munro's duty these five years without having any allowance although I recollect your telling me that if required to practice I would have 100 pounds, i.e., Dr. Munro's salary. Now the first year I came here Dr. Munro's time was out and tho I was oblig'd all along to do his duty . . . yet they engag'd him and gave him the salary that was promis'd to me . . . the 2nd year . . . I was requir'd to practice while he was sent to an Indian post . . ."

Again he writes on July 13, 1808, from Fort William that he was offered 150 pounds but rejected it because it was "less than Dr. Munro, although I had served an apprenticeship to them of five years for 100 pounds, whereas Dr. Munro had a hundred a year the first four years and two hundred every year after . . ."

Several years later, on August 2, 1810, he wrote the following from Fort William: ". . . even when Dr. Munro was in the country I act'd always as surgeon . . . he only act'd now and then when he happened to be here."

After the Northwest Company was absorbed by theHudsons Bay Company in 1821, Dr. McLoughlin became celebrated as a fur trader and pioneer in the Pacific Northwest. He has been called "The Father of Oregon." The story of his life, "The Whiteheaded Eagle—John McLoughlin—Builder of an Empire," is much more interesting when the reader realizes that he got his start as a surgeon and fur trader in the wilds of northern Minnesota.

In 1826 Governor Cass of Michigan territory came to Fond du Lac to complete a treaty with the Indians. In his party were Henry Schoolcraft, Major McKenny, and Dr. Zina Pitcher of the U. S. Army, along with some soldiers and voyageurs.

Major McKenny[5] kept a diary, which was afterwards published, and in it he recorded the first medical case history within the present limits of Duluth. For July 31, 1826, Major McKenny writes: "I visited today, on the island, in company with Dr. Pitcher and our interpreter, an Indian girl who is afflicted with hemiplegia. About four months ago she was taken with a severe pain in the back of the neck, which, in turn, was soon followed by a complete paralysis of the left half of the body and entire loss of sensibility of the optic nerve, a total amaurosis." This liberal use of medical terminology is explained when the author states that these details were given him by Dr. Pitcher, who made a very careful study of the case. Three days later the doctor applied a cup to the back of the neck: "The blood was very sluggish and dark but the pain was somewhat relieved." The same evening there was further cupping to the right temple and on the following morning cupping to the left temple: "Here the blood flowed more freely and was brighter in color." Food, bedding and better care helped to improve the patient so much that, when the expedition left on August tenth, the doctor was able to report that "there was every prospect of the patient recovering completely, except that her blindness must remain." Dr. Pitcher served in the army from

1819 to 1836, when he located in Detroit, and became well known in state medical affairs.

In 1832 Schoolcraft undertook an expedition to find the source of the Mississippi, and was accompanied by Dr. Douglass Houghton and Lieut. Allen of the army, along with a small detachment of soldiers and voyageurs. Dr. Houghton, in addition to his duties as surgeon, was to vaccinate the Indians along the route and make botanical and geologic observations. At Fond du Lac, which is within the present city limits of Duluth, Dr. Houghton vaccinated two hundred and forty-three Indians. He writes: "In nearly every instance the opportunity which was presented for vaccination was embraced with cheerfulness and apparent gratitude. The efficacy of the vaccine was well appreciated even by the most interior of the Chippewa Indians." No doubt the Indians of that period were well aware of the terrible scourge of smallpox which occurred at Fond du Lac in 1782. Dr. Houghton later became well known in Michigan. He was a practising physician in Detroit; the first state geologist; mayor of Detroit in 1842; a professor in the state university. In 1845, while employed on a government survey, he was drowned in Lake Superior.

The expedition of 1832 made two notable contributions: first, it was successful in discovering the source of the Mississippi; second, the report of Lieut. Allen[1] to the War Department contains an episode which is of interest in that it is probably the first "compensation case" recorded in what is now Minnesota.

The portage above Fond du Lac, which was also called "Grand Portage," was a very difficult one. Today, in driving through Jay Cooke Park, one can visualize the hazards in carrying canoes and provisions over the nine miles of rough country. It was on this portage that a soldier named Beemis, while climbing up the steep river bank fell, with a keg of pork on his shoulder, and injured his back. Beemis was kept in the hospital for more than a year after his return to civilization, and subsequently discharged at Fort Dearborn (Chicago) on a surgeon's certificate of disability.

There were, no doubt, many other medical men of this period who traveled in northern Minnesota, but they left no record of their impressions or mark as physicians. On the first expedition of Governor Cass and Schoolcraft in 1820, a Dr. Alexander Wolcott[6] was surgeon. He was also Indian agent at Chicago, but it does not appear that he made any report of his work as surgeon of this expedition. At a later date, there is record of a young clerk, a physician, who was stationed at Leech Lake in 1833-34, in the employ of a fur trader. In "Letters on the Fur Trade"[6] the following is of interest:

> "My companion for the winter is a clerk; a hot headed Irishman; who has received a liberal education; and was by profession a physician, but he had turned all these advantages to his disadvantage. His art was used to gain the good will of the Indians, for they generally look up to such with a great deal of respect; and not a day passed without extracting teeth and bleeding, and our having a small quantity of medicine which was freely administered to all who applied for it; and the dread and respect they have for medicine men, naturally drew respect from them, and they formed the opinion that our medicines were combined, the white and Indian together. Everything aided to win the respect and esteem of our Indian friends; and my companion, being an excellent musician, we had the means of soothing their savage breasts, although frequently there was only two strings to the violin."

The last of the doctors of the fur trading period in this locality was Charles William Wulff Borup, who for many years was the only trained physician west of the Sault Ste. Marie and north of Fort Snelling. Dr. Borup was born in 1806

in Copenhagen, Denmark, where he received a thorough classical and medical education. He came to the United States in 1828, and was employed by the American Fur Company in 1834, in which he eventually became chief agent on Lake Superior. His headquarters were at La Pointe, although he traveled extensively along the south shore of Lake Superior, and as far west as Leech Lake. Although primarily engaged in fur trading, as were Munro and McLoughlin, Dr. Borup kept up his interest in the practice of medicine, as the records of the American Fur Company will show. He was a subscriber to the *American Medical Journal,* which was sent to him from Philadelphia via the Erie Canal and the Great Lakes to the Sault, there by canoe to his post on the south shore of Lake Superior or on the St. Croix. His order to the New York office of the American Fur Company for February 28, 1835, called for:

"1 good tooth drawer
1 dz. bougies in set
1 lb. camphor
2 ounces Quicksilver
½ lb. cantharides in powder
I ounce sulphur antim. praecepitatum
1 pint spiritus Pennyroyal
½ ounce aleum caryophyl
1 bottle Carpenter's Compounded Syrup of Liverwort
2 Gross vials assorted with corks"
and other similar items

On May 11, 1841, he writes:

"I wish to purchase a newly invented instrument (if it may be called so), the intention of which is preventing the cold air from affecting the lungs. It consists in a kind of mouth covering, furnished inside with metallic springs, through which the air is drawn into the lungs. It is to be had in the principal apothecary shops in Broadway . . . there are two kinds, one for ladies and one for gentlemen."

Dr. Borup settled permanently in St. Paul in 1848, where he died of heart disease on July 6, 1859.

Smallpox in Minnesota

MINNESOTA has been experiencing an increase in the usual number of cases of smallpox, which in the past two months has reached the status of a mild epidemic in certain quarters. From the fourth of December until the middle of January, about one-half (149) the total number of cases reported (286) had occurred in Saint Paul with Clay, Pine, Yellow Medicine and Lac qui Parle Counties suffering next in the order mentioned. Strange to state, during this six weeks' period no case was reported from Minneapolis and only one from Duluth. This is quite the opposite of what occurred in 1924 when a laborer from Canada, suffering from malignant smallpox, started an epidemic in Duluth. Minneapolis was severely affected that year and Saint Paul but little. There were 307 deaths from smallpox in the state in 1924, and 198 deaths in 1925. So far, fortunately, there have been no deaths in Saint Paul from the disease.

Each year there are a certain number of cases of smallpox in Minnesota. In 1935 there were 284, in 1936 there were 397, and in 1937 a total of 665. The increase in 1937 was noticeable throughout the last nine months of the year, and particularly in December.

The increase in cases over last year holds true for the country at large. Reports show that this increase has taken place for the most part in the central and north central states and in those states west of Minnesota as far as the Pacific Ocean.

Certain states, notably Massachusetts, have compulsory vaccination laws. Most of our states are content to await the arrival of an epidemic, when regulations requiring vaccination for attendance at school act virtually as a compulsory requirement and stimulates general vaccination. In the interim between epidemics the public becomes lax and the soil becomes fertile for another epidemic.

While smallpox can be almost entirely prevented by vaccination, it is not generally appreciated that a certain number of cases develop in individuals who have been successfully vaccinated. In 1924, for instance, there were in Minnesota 327 cases of smallpox with forty-seven fatalities in individuals who had been successfully vaccinated more than seven years previous to their infection. The importance of revaccination every seven years is therefore demonstrated.

Incidence of Syphilis

AN ACCURATE determination of the prevalence of syphilitic infection is admittedly difficult. However, some of the statements which have appeared recently in magazine articles are gross exaggerations. In articles which appeared in the *Readers' Digest* last year, Parran referred to syphilis as our No. 1 American

killer, and Stokes stated that the disease ranks high if not first among causes of death in this country. In the *Pictorial Review,* Maxine Davis referred to syphilis as the greatest killer of the day, and stated that the leading authorities say that three million sufferers stand in need of treatment each year. Certainly statistics, inaccurate though they may be, do not substantiate such statements.

Studies undertaken by the American Social Hygiene Association and the United States Public Health Service have shown that approximately half a million individuals seek treatment each year and that about 68,300 cases of syphilis are under treatment at any one time. This corresponds to the number of new cases tabulated by the various State Boards of Health, which amount to about half a million. Positive Wassermann reports not designated repeats are considered new cases, but we suspect all such cases are not new because of inaccuracy on the part of reporting physicians. On the other hand many individuals contract the disease unwittingly, resort to drug store medication or seek the services of irregular practitioners and are not recorded. One estimate, that this group of unreported cases amounts to double the number recorded, we consider a rash overstatement. This may have been true years ago, but the number of individuals who seek advice as to the presence of the infection needlessly, incline us to believe that the number of undetected cases does not nearly equal those recorded.

Surveys of various groups have shown a variation from 1 to 25 per cent in positive Wassermann reactions. According to Snow, 5 per cent is probably a conservative estimate for the population as a whole. New infections reach their peak in the age group from twenty to twenty-five and half the infections occur between twenty and thirty years of age. According to the Metropolitan Life Insurance Company, their mortality from syphilis is four and a half times as great in colored as in white males, and six times as great in colored as in white females.

What can be said of the incidence of syphilis in Minnesota? A few years ago 5,000 students at the University were examined and only ten positive Wassermann tests were obtained (0.2 per cent). This, of course, was a selected group and one which had not gone far into the age period when the incidence of infection reaches its peak.

According to the Census Bureau, about six per 100,000 of population died yearly from syphilis in Minnesota during the period of 1932 to 1936. During those same years about 130 died each year from cancer and from 197 to 251 each year from heart disease. To make the comparison more striking, the total deaths in the state of Minnesota in 1936 attributed to syphilis were 162 compared with 3,519 due to cancer, and 6,619 due to heart disease. Allowing considerable leeway for errors in reporting, syphilis is far from heading the list of killers in Minnesota. As a matter of fact, it ranks about eleventh in the nation as a whole.

Minnesota was one of the first states to institute a program to fight venereal disease. In 1918 the activities instituted in connection with the war to control the disease were made permanent. Syphilis was made reportable and free Wassermann testing was provided by the State Board of Health. The foundations were laid twenty years ago for what is today considered essential to venereal control. It is safe to conclude that there has been no falling off in the reporting of new cases to the State Board of Health in recent years as the number of Wassermann tests performed by the State has shown a steady increase until 83,000 were made in 1936. That syphilis in Minnesota has been on the decline is shown by the fact that in 1925, 5,147 new cases were reported and in 1936 only 3,379. This is in keeping with the steady decline in deaths among white policyholders from 1923 to 1930 reported by the Metropolitan Life Insurance Company, a reduction which has been maintained since 1930.

Syphilis, then, is not so serious as a cause of death, as has been stated. It is, however, among the leaders as a cause of human misery. Syphilis in its congenital form, as the cause of heart disease and central nervous system disease and, fully as important, the rôle it plays as a destroyer of the home, places it in the front ranks of the enemies of mankind. If the recent publicity campaign serves to further early diagnosis and treatment, it will have been worth while.

MEDICAL ECONOMICS

New Deductions for Doctors

At the request of the State Medical Association, the Minnesota Tax Commission has reviewed the deductions allowed physicians in making out state income tax returns.

The result of this review is a new ruling made by the Commission, Jan. 21, 1938. According to this ruling, physicians may make the same reduction in their state income taxes, for expenses incurred in attendance at medical meetings and in other postgraduate medical education, as are now allowed under the federal income tax.

Concurring in the ruling were H. E. Boyle, chairman; G. E. Wallace and G. F. Gage, members of the Commission, and W. G. Burkman, director.

A Recent Visit to Buenos Aires

Most of us North Americans have a vague idea of what is going on in the other half of our Siamese Twin south of Panama. South America has always seemed so remote that we never have given it much thought. What we know about it has been learned largely from news reels and movies, such as "Flying Down to Rio." A Cuban, Mexican, or South and Central American all looked alike to most of us, and we carelessly put them all in the same group. I am afraid that my idea of their level of culture, including medicine, was none too high before my recent visit to South America.

Comparatively few Americans from the north have visited the southern half of America in the past. In the year 1936, 12,000 tourists left the United States for South America and 250,000 for Europe. The number was increased last year, but even so, there are all too few. The greatest handicaps have been the distance of 5,000 miles to Rio de Janeiro and 6,000 miles to Buenos Aires, and slow, inadequate passenger boats. This has been greatly overcome by the highly efficient Pan-American Airways, and there will soon be better and faster boats. The number of visitors from South America to the United States has doubled in recent years and in the future will undoubtedly be even greater. Great interest in the United States has been aroused in South America by our movies, autos and radios, and they are bent on knowing us better. This is also true in medical circles.

Tide Has Turned

In the past physicians in the Latin-American countries have naturally gone to Europe for graduate training. Since the Great War, and as a result of the current unrest and disturbance in Europe, the tide of graduate medical interest has turned to North America. They are aware of our advances in many fields of medicine and are coming in rapidly increasing numbers to study and learn. It is up to North American medicine to be prepared to offer every opportunity to our South American cousins.

Having received an invitation to attend a meeting of the Pan-American Urological Congress in Buenos Aires, after some hesitation I decided to go and I am glad that I did. Although much time is consumed in the voyage, the journey is most pleasant in every way.

When we finally docked one fine summer morning in December at Buenos Aires, I was due for a series of overwhelming surprises. In the first place, I was fairly swept off my feet by the generous hospitality of our hosts. Argentinians are a wonderful people, virile and progressive, and they will undoubtedly be a large factor in the future development of South America. They are inordinately proud of their great city of

Buenos Aires and the vast resources of Argentina, and rightfully so.

Melting Pot

Let us first glance at Argentina, which has an area of one-third that of the United States, extending some 3,000 miles from Terra del Fuego to a few degrees below the equator, having both an antarctic and subtropical climate, at either end. It has some 13,000,000 inhabitants—almost entirely white—made up of Spanish, with some mixture of Irish, Scotch, British and Indian, who were the early inhabitants. In the last twenty years these were augmented by millions of Italians, Germans and other European immigrants. It is even more of a melting pot than the United States. It is surprising to note how quickly most of the immigrants and all of their children adopt the Argentinian ways, speak Spanish, and become intense patriots of Argentina. Their main resources and wealth lie in the millions of acres of pampas lands, with soil so rich that fertilizing is quite unnecessary. The millions of cattle and the great wheat fields are turned to gold, so that Argentina knows no depression and no unemployment.

Their great capital, Buenos Aires, is a vast city of some 3,000,000 people. With its beautiful buildings, great squares and wide boulevards, wonderful parks and playgrounds, it is one of the most beautiful cities in the world. The Paris of South America, it has been called. It might be almost as appropriate to say that Paris is the Buenos Aires of Europe.

Standards are High

As far as the medical status of Buenos Aires is concerned, I was surprised at the high standards of medical care in that great city. The leaders of the medical profession are well informed, progressive, intelligent and alert to recent developments. Among the many outstanding men of medicine who have received international attention may be mentioned Chutro, Arce, Finochietto and Gutierrez in surgery; Castex, Boneo and Roffo in medicine; Valls in orthopedic surgery, and Saraleguy in roentgenology. Among the various scientists engaged in premedical work is Houssay, head of the University Institute of Physiology. This great scientist has done outstanding work in physiological investigation on the influence of the pituitary on the pancreas and their interrelationship with the hormones of other endocrine glands. Among the honors he has received is an LL.D. from Harvard last year.

The work of Roffo in regard to the cause of cancer has attracted considerable attention. He thinks he has proved that tobacco is a direct cause.

Medicine in Buenos Aires centers around the great medical school. A vast new building with teaching hospitals is in the course of erection, which will cost $10,000,000. It will be the last word in construction to facilitate modern methods of medical instruction. The standards of education are high.

There are three other large medical schools in Argentina, at La Plata, Rosario and Cordova. These, together with the university at Buenos Aires, graduate some 2,000 students annually. Since a large portion of the public is able to pay very little for medical services, the economic opportunities for the recent graduate are none too good.

Vast National Resources

The economic status of the inhabitants of Buenos Aires, as well as of all South America, is somewhat comparable to that observed in France, Italy and other Latin states. Although the natural resources are vast beyond description, they are undeveloped and as a result the opportunities for earning a livelihood are inadequate. Therefore, labor is cheap and there is a large class, in proportion to the population, which is underpaid and living on very little. Fortunately, climatic conditions are favorable and the bare necessities can be obtained for comparatively little. Since the low income group makes up a large proportion of the population, medical practice is necessarily adjusted accordingly. Many of the people are able to pay but little for clinical care and even less for hospitalization, and the government is forced to care for them. As a result, most of the hospitals are charity institutions. Private hospitals, or sanatoria, as they are called, are few in number and inadequate. Although many of the government hospitals are well conducted and the medical services are adequate, the medical and nursing care in most cases would hardly meet the demands of the average citizen of the United States.

Government Medicine

In some of the institutions controlled by the government the service is either inadequate or extravagant. As an illustration of the inefficiency of government control, an institution was erected by the city to take care of roentgenographic diagnosis and radiotherapy for all the hospitals and dispensaries. The institute is controlled by a competent and excellent roentgenographer. However, his assistants, appointed by the government, fail to coöperate with him and as a result there is considerable confusion and the service is often unsatisfactory. On the top floors of the building, which was completed some seven years ago, there are wards with seventy-two beds, fully equipped for radium treatment, but for various reasons means have not been found to employ the two grams of radium which is available. As a result, these wards are taken care of—dusted and cleaned every day, but no patient has ever appeared. On the same floor there is a beautifully equipped room to be used as a library, and the shelves have been bare these seven years because no books have been provided. There could be no more striking illustration of the fallacy of government medicine.

The hospitals are for the most part old and built in the pavilion style. The Rawson Hospital, recently erected, is a fine example of a well equipped hospital, having more than 2,000 beds. Many new hospitals are being planned or are in the course of construction to take the place of those which are old and inadequate. The hospitals are of three types, federal, municipal, and private. The federal hospitals are largely for the care of patients with chronic illness, and, in particular, female patients and children. They are controlled by a national committee composed of fifty women. These institutions are supported largely by proceeds of the Federal Lottery. Fifty per cent of total earnings are devoted to this charitable purpose. This sum is augmented by 10 per cent of the proceeds of the Jockey Club, derived from wagering on the horse races. Since the passion for gambling is prominent in the Latin soul, the Argentinian government believes that it is best controlled by giving it legitimate opportunities for gratification. Since the government derives enormous profits and the public is satisfied, this solution of the problem of hospital support is a very happy one. In fact, one wonders if it could not be adopted in succoring the financial anemia of some of our hospitals.

Tuberculosis Care Thorough

There is a large neurological institute which has an outstanding staff of scientific investigators. The care of pulmonary tuberculosis is on a large scale and is very thorough. A surprisingly large number of patients are subjected to phrenectomy, pneumothorax and thoracoplasty.

One criticism which I heard several of the clinicians make was that the clinical material in the various hospitals was divided into so many separate services that the amount in each service was limited to such an extent that the possibilities for clinical investigation were scarce.

Although the government has a very paternalistic attitude toward the medical indigent, no definite attempt has been made to set up state medicine as it exists in many of the European countries. The medical profession is not as closely organized as we are in our own country, but they have been able to exert considerable influence in a personal way and do not seem to fear the European form of state medicine. Some of the profession claim that investigation as to the ability of the patient to pay is very lax. There is comparatively little social service work being done there, although plans are being made to develop this field in the future.

The majority of the medical profession as a whole could be said to compare favorably with our own. There is a great desire for graduate training and in the future we will undoubtedly see many Argentinians visiting our clinics and attending medical meetings in North America. We should extend to them every available encouragement and coöperate with them to our fullest ability.

* * *

I have not referred to the short visit I made in Rio de Janeiro and Sao Paulo in Brazil, and to Montevideo in Uruguay. Sufficient time was not available for a thorough study of medical conditions.

In closing I can heartily recommend a trip to South America as being a most enjoyable and interesting one, and in many respects more instructive than a visit to Europe.

W. F. Braasch

Malpractice? Supreme Court Says "No"!

The Supreme Court of Minnesota has recently decided a malpractice case that we are sure will interest the medical profession. The opinion was written by the Honorable Harry H. Peterson, Associate Justice, and held that the plaintiff could not recover in that particular case.

The plaintiff sued a number of physicians in Minneapolis for malpractice, following a severe injury sustained in an automobile accident. The plaintiff suffered a fracture of the femur of the right leg which, as the Court pointed out, "is a very severe bone injury." The plaintiff suffered some discomfort and pain and a pressure sore on the heel from the cast. This work was done between December and the following March. Along in June of the same year the plaintiff developed an infection in the great toe on the right foot, resulting in amputation of a part of the toe.

Justice Peterson, in his opinion, stated that it was admitted that the defendants possessed the requisite skill and learning as physicians and surgeons. The question before the Court was whether or not they were negligent in applying their skill and learning in this particular case. The opinion points out that there was a total absence of any evidence that the practice by the defendants was not in accord with the usual and accepted medical standards. The opinion further points out that

"the highest degree of care was exercised in applying the cast and that notwithstanding such care in this case, as often happens in other cases, pressure sores unavoidably develop."

The Court held that a physician is not liable for injuries unavoidably resulting in spite of the exercise of due care, the Court pointing out:

"A physician or surgeon is only required to possess and exercise the degree of skill and learning ordinarily possessed by members of his school of the profession in good standing, and to apply that skill and learning with reasonable care and diligence and his best judgment."

The opinion further states that the defendants are not liable unless the plaintiff proves that the injuries complained of were the proximate result of negligent acts on the part of the physicians. The Court pointed out that the injuries, other than the heel sore and the pain resulting therefrom, and the stiffness in the leg, did not result from the treatment of the bone fracture; that the plaintiff was suffering from arthritis when he was admitted to the hospital. After the plaintiff failed in his proof of the charge of malpractice he advanced the theory of a technical assault and battery because the second cast was not put on the way the plaintiff thought it should be put on. The Court held that where a plaintiff proceeds against a physician on the basis of negligence and the matter is submitted to the Court upon that issue, he cannot thereafter, in a motion for a new trial, raise, for the first time, the question of assault and battery.

The decision of the Supreme Court was unanimous and the opinion written by Justice Peterson shows, very clearly, that the entire matter received the close scrutiny of the Court. The opinion contains many citations of other cases and a thorough discussion of the most minute details of the present case. A careful reading of the opinion indicates that same malpractice suits are instituted even though the facts and the law show, rather definitely, the absence of merit in the law suit.

This case was first tried in the District Court of Hennepin County before the Honorable Arthur W. Selover, Judge, and a jury. After hearing the evidence, Judge Selover was of the opinion that the plaintiff had not proved any malpractice against the defendants and consequently directed the jury to bring in a verdict for the physicians.

NOTE: Justice Peterson will be remembered by many members of the medical profession as an efficient and aggressive Attorney General of the State of Minnesota from 1933 until his appointment to the Supreme Court in December, 1936.

The Lay Demand For Medical Publicity

The medical Box of Pandora has been opened to the prying eyes of the laity and its medical secrets are now making the front page. It is difficult to pick up a magazine today which does not

contain an article pertaining to some phase of medicine.

When one reflects on the publicity given by the daily press alone, often in screaming headlines and written in sensational style, with its exaggerations and distortions of half-truths, one wonders if the old way of thinking would not be best for all concerned. While information concerning disease in certain fields may be of benefit to the public welfare, unless the subjects are carefully selected and written up by competent medical authorities, resulting misinformation may to a great extent overcome any good which might come from such publicity.

By Incompetent Writers

Unfortunately, many articles now flooding the periodicals are written by incompetent lay writers and in some instances by an incompetent medico. Under the guise of giving information to the layman, who has been "kept in abysmal ignorance throughout the ages," a choice lot of balderdash is being dished out to the gullible public. By using catch phrases and playing up sex features, popular interest is attracted and much of the misrepresentation and distortion of facts is believed. Some of these articles will have sensational headlines or illustrations which suggest criticism or inadequacy of the present methods of medical care. In some cases the substance of the article will correct this to some extent, but the casual reader will retain only the superficial impression.

Dressed Up to Catch the Eye

As an example of misinformation which is even worse than the secrecy of yore, attention is called to an article on prostatic disease which appears in the current issue of *Pictorial Review.* Written by a layman and dressed up to catch the public eye, it contains many statements which are controversial and far from exact. To give the article an air of authenticity, it quotes liberally from a well known authority on prostatic disease, so editing his remarks as to substantiate the text of the article. This may well serve as a warning to our profession to beware of the magazine interviewer and to inquire as to the purpose and scope of the proposed article. Circumstances may be such that a request by authorized reporters for information regarding medical subjects should be granted. If so, it is wise always to insist on editing the copy before publication, and not to contribute pictures of oneself in the course of an operation or examination.

Many similar articles can be cited. As a result of the mass of misinformation, the public probably will be more confused than it was before the campaign was started. Something should be done about this.

Relief Clients May Choose—
Aufderheide

The month of January brought negotiations in many counties about medical relief for 1938.

In several, commissioners and boards of welfare disagreed with representatives of physicians as to the meaning of the clause in the Relief Law that provides "choice of vendor" to relief clients, providing the vendor lives up to regulations and qualifications.

The meaning of the law is clear. The State Relief Administration properly interprets it to refer to vendors of services as well as products, and will enforce that interpretation in every county that receives aid from the state to handle its relief problem.

In complying with this law it makes no difference how individual counties allocate their funds. They may choose to declare that medical relief bills are paid out of local funds and so hope to evade the law; but relief administrators do not recognize such distinctions and are prepared to refuse state aid to offending counties.

To Send Bulletin

A bulletin to this effect will go out shortly from Mr. Herman D. Aufderheide, State Relief Administrator.

Unfortunately the relief department does not feel that it can make the same demand for payment of the fees called for by the official S. R. A. fee schedule.

Fees Another Story

Mr. Aufderheide says that funds to pay the fees are adequate. The fees should be paid; but he cannot enforce payment. In several counties certain modifications have been made in confer-

ence between physician representatives of local societies and the county commissioners or welfare boards. In case of disagreement it appears to be a problem that can be settled only in such conferences. Happily the full schedule is being paid without question in many other counties. A questionnaire is going out from the State Office soon to every county in the state to find out exactly how satisfactory relief arrangements are in Minnesota.

Keener Vision

(Monthly Editorial by the Medical Advisory Committee)

An advertisement in a lay magazine advises that squinting, frowning, or scowling when using the eyes is usually an indication that the eyes need attention, better light, or both. Webster defines these words as follows:

To squint: to have the vision distorted.
To frown: to contract the brows in displeasure.
To scowl: to look sullen or angry.

The need of clearer vision and keener insight into the other man's problems has never been more apparent than in the cases reviewed by your Medical Advisory Committee during the last year.

The squint, the frown, the scowl each have a degree of meaning to the observant person. As the dissatisfied patient of another doctor hangs on every word of his present consultant, so he sees and registers every expression of pleasure or displeasure on the consultant's face.

The average consultant before a malpractice suit does not see the patient until several months after the original injury complained of. Therefore, before giving a positive opinion by look or word, would it not be advisable to obtain all the light possible on the case as procured by the first man, even to the point of a telephone call or personal interview with him?

An hour spent in the study of psychology and economics in the handling of patients could well become a part of every medical man's day.

Visiting President

Mrs. Augustus S. Kech of Altoona, Pennsylvania, is national president of the Women's Auxiliary and legislative representative and advisor of the Pennsylvania State Medical Society.

She visited the Twin Cities recently, talked to the Ramsey and Hennepin County auxiliaries, to a group of officers of the Minnesota State Medical Association, proved to everybody who met her that she is a person of unique charm, energy and a remarkable grasp of the political and economic problems of medicine.

Pennsylvania's Troubles

What she told the doctors about the difficulties of the Pennsylvania soicety in handling its cult problem was of especial interest to Minnesota.

Said Mrs. Kech in substance:

There is a Medical Practice Act in Pennsylvania; but it is not enforced. The result is that approximately 200 chiropractors are licensed under the Act and 2,700 are practicing without licenses and in defiance of the law.

(Compare these figures with Minnesota figures for chiropractors under the Basic Science Law, 1927 to 1937. In April, 1927, 592 were registered. Since then thirteen have passed the Basic Science examinations and three have registered by previous licensure. In 1937, however, only 398 were registered and any chiropractor who attempts to practice without a license is subject to prompt prosecution for violation of the law.)

The 2,900 chiropractors in Pennsylvania were assessed $100 each for legislation last year.

That produced a fund of approximately $300,000 for the chiropractors alone last year.

To combat it, the Pennsylvania Medical Society secured the services of twenty lay speakers, trained them and sent them out to talk to every group in the state, from the smallest sewing circle of ten persons to large public gatherings.

Every one of 141 cult bills was killed as a result of this intensive work, and in spite of the fact that the lower house of the Pennsylvania legislature was so organized that it was impossible for the physicians to work with it.

Auxiliary Help

The Auxiliary helped greatly by clipping newspapers and periodicals throughout the state for editorials, news stories, items of interest that bore in any way upon medicine or the legislative situation.

Minnesota State Board of Medical Examiners

Minneapolis Woman Sentenced to Five to Twenty Years at Hard Labor

Re: State of Minnesota vs. Myrtle L. Brandenburg.

Myrtle L. Brandenburg, who holds no license to practice any form of healing in the State of Minnesota, entered a plea of guilty on January 6, 1938, in the District Court of Hennepin County to an indictment charging her with manslaughter in the first degree. The defendant was sentenced by the Honorable Levi M. Hall, Judge of the District Court, to a term of five to twenty years at hard labor in the Women's Reformatory at Shakopee.

Mrs. Brandenburg, who stated she was thirty-seven years of age, and the mother of three children, performed a criminal abortion on a twenty-seven years old married woman who died from the effects of the abortion on November 23, 1937. The defendant resided at 664 Fourth Avenue, Northeast, Minneapolis, and has been under suspicion for some time for being in this type of criminal work. She admitted that she had performed other abortions, stating that she received $25.00 apiece for a few of them, but that most of the time she received from $5.00 to $10.00 per abortion. She also was practicing medicine unlawfully by furnishing pills and other medicines to the patients. She used a chromium plated catheter and elm bark as her chief weapons, and these were found by Minneapolis policewomen, hidden in the radio in the Brandenburg home.

Mrs. Brandenburg has had no medical training of any kind. This case again illustrates the terrific penalty paid by lay people who go to quacks who have no knowledge of anatomy or of the absolute necessity of sterile conditions. The prompt and effective disposition of the case is due, in great part, to the splendid work done by the Women's Bureau of the Minneapolis Police Department and the coöperation shown by the Coroner's office under Dr. Gilbert Seashore, and the County Attorney's office. The imposition of this sentence by Judge Hall should be a warning to a number of individuals in Minneapolis that the law does catch up to them and that the penalty can be made quite severe.

Distribution of Smallpox Vaccine

So far as very limited funds will permit, smallpox vaccine will be distributed for use in school or other public vaccination projects, the plans for which have been approved by the County or District Medical Society, and particularly in districts where smallpox has appeared. Requests for vaccine should be accompanied with a statement of facts and that the County Society approves the plans. The date on which the vaccinating is to be done and the number of persons to be vaccinated should be given.

It is important for all group immunizations, or in any case where the parents are not present, that the written consent of the parents be first obtained. Cards for such purpose will be furnished by this Department on request. Only as much vaccine as is immediately needed should be asked for and any unused tubes promptly returned.

The funds available for the purchase of vaccine are quite small. Vaccine must be kept at all times in an icebox. Its potency is less than 90 days. This Department cannot get any credit for outdated tubes nor can outdated tubes be exchanged for fresh vaccine. So the purchase price of an unused and outdated tube is a total loss. In consideration of these facts and the money available, it does not seem possible to furnish vaccine to physicians for use in their regular routine private practice.

MINNESOTA STATE DEPARTMENT OF HEALTH.

In Memoriam

Charles Patrick Dolan

1858-1937

DR. CHARLES P. DOLAN died at his home in Worthington, December 23, 1937 at the age of eighty.

Dr. Dolan's parents were among the early settlers in Waseca County, having homesteaded there in 1858. On the old farm, where his parents lived continuously to ripe old age, Dr. Dolan was born September 8, 1858. After attending the county grammar schools, Dr. Dolan later graduated from the high school at Waterville.

Beginning with a year in the office of Dr. E. P. Case of Waterville, Dr. Dolan received his medical degree from the University of Iowa, Iowa City, in 1880 and took a year of postgraduate study at Bellevue Hospital, New York City. Beginning practice in Waterville, he moved to Worthington in 1904.

On January 25, 1888, Dr. Dolan married Tillie McElvoy, a native of Illinois. Two children, Leo Dolan of Worthington and Marie (Mrs. Howard Thrush) of East Chicago, Indiana, survive.

Dr. Dolan has been one of the leading physicians of Nobles County since 1904, when he moved to Worthington, taking over the practice of his brother, Dr. Edward Dolan, who died that year. He was the first president and charter member of the local Kiwanis Club, vice president and one of the original members of the Southwestern Minnesota Sanatorium commission, and for many years county coroner and health officer for Worthington. He owned a cabin in northern Minnesota where he loved to seek diversion in hunting and fishing. During his many years of service, he had endeared himself to his many friends and patients.

Frank Benjamin Hicks

1860-1937

THE death of Frank Benjamin Hicks, of Grand Marias, Minnesota, who passed away at University hospital, Minneapolis, August 21, 1937, marks the closing of a pioneer medical career, which has been compared by many to that of Dr. Wilfrid Grenfell of Labrador.

Born May 3, 1861, at Tomah, Wisconsin, the eldest son of Rev. and Mrs. William C. Hicks, he first chose the ministry as his career. Making his own way, he graduated from Beloit Academy and later received his B.A. from Beloit College. From there he went to the Chicago Theological Seminary, graduating with his B.D. degree in 1888.

During summer vacations, he supplied in missions in the then Dakota Territory. While there he met Miss Ethel M. Barnes, a school teacher, whom he married in

August, 1888. His pastorates were near Chicago, enabling him to study at the University of Chicago, where he took his M.A. and Ph.D. degrees in history.

A man of vision, he was a bit before his time in that he wished to develop reading and recreational centers in the church. All such activities were considered undignified and not a part of a clergyman's affair by most church fathers. Mr. Hicks finally decided he could do more good for humanity in the practice of medicine. So, with his wife and four small children, he gave up his prosperous church and took two small missions outside Chicago, having only $200 in cash assets.

Preaching Sunday mornings at Genoa Junction, Wisconsin, and in the evening at Richmond, his wife taking charge of the evening service in Genoa and the midweek prayer meeting, Mr. Hicks went to Rush Medical College, graduating with honors in June 1898, in debt but a little over one hundred dollars.

In October, 1898, Dr. Hicks moved to Washburn, Wisconsin, where he began the practice of medicine.

In 1906, he moved to Grand Marais, Minnesota, as physician for the lumber camps. At that time there were thousands of men in the lumber camps and he visited each camp once a month unless called oftener. He supplied hospital care for those who needed it. These trips were made with horses and bob sled, or on horseback. A trip to the camps required three days' time.

In 1907, he was appointed government physician for the Indians of that district, a post which he held until his death. Until the last years of his life, he was never off duty for illness but four days and in all those years his only vacation was one of three weeks' duration.

In those days, travel by road in summer time was practically impossible and he made his trips by way of his small motor-boat up and down the shore on treacherous Lake Superior, often having narrow escapes with his life. Trips inland were made as far as possible on horseback or driving himself. Then taking a canoe he would paddle across a lake, and with the canoe on his back, his medicine case in his hand, make a portage of from three-fourths of a mile to three miles, launch the canoe and paddle on. On one of his calls he made fourteen such portages. In the winter, he used dog teams. At another time, he walked fifty-eight miles to the bedside of a very sick and penniless woman. He brought hundreds of children into the world and in spite of the crude conditions he had to work under, never lost a mother. He often had to act as a nurse as well as doctor. In a few instances, in the absence of another clergyman, he performed the burial service for those in out-of-the way places, and on one occasion also during a smallpox epidemic when the clergyman refused to officiate. For twenty-five years he was the only doctor within a radius of ninety miles. The large lumber camps were there but two years and after that the greater part of his work was done for "love of humanity."

In 1913, he was appointed by Governor Eberhardt to the Minnesota State Board of Medical Examiners, a position which he held for several years, acting as president for one year.

When the coast guard was instituted at Grand Marais he was made their physician.

Everything he could do for public good he did gladly. Largely through his efforts a high school was established in Grand Marais. The Congregational Church there was founded by him and later he was an important factor in the "good roads" movement.

He was passionately fond of music and his hospitality was a by-word among all who knew him.

By his side a constant source of help and encouragement through all the years, stood his wife.

Dr. Hicks is survived by his widow and four children: Dr. Harvey R. Hicks of Grand Marais; Mrs. Hester Temple of Blue Earth; Mrs. Celia Valentine of Ely; and Mrs. Elizabeth Roberts of Cleveland, Ohio. Mrs. A. Tymeson, of Minneapolis, is a sister.

It may well be said that here was a life dedicated to "Service," where any who asked might receive.

Mineral Oil in Foods

The Council on Foods reports that it is well known that liquid petrolatum is not absorbed from the gastro-intestinal tract, and that it yields no calories. Because of these properties, mineral oil is extensively used in the treatment of constipation and, to a lesser extent, in replacing fat in certain foods, chiefly mayonnaise and salad dressings, and a few other products. According to published reports mineral oil interferes with the utilization of vitamin A by experimental animals. Later reports indicated that the ingestion of mineral oil resulted in a considerable loss of vitamin A to the animal organism if the oil was administered with the source of vitamin A but not if the mineral oil was given at some other time of the day. It was also brought out that different results could be expected with different sources of vitamin A. It is apparent that liquid petrolatum would be a poor vehicle for vitamin A and particularly for provitamin A, and its use in this connection could not be countenanced. On the other hand, it appears that in the amounts usually prescribed and under the conditions which should be observed (not to be taken at mealtime), the effect of liquid petrolatum on the absorption of vitamin A of the human diet probably is of little consequence. When incorporated in foods, however, so that the mineral oil is taken at mealtime, it is obvious that there is danger of interference with the absorption of the fat soluble vitamins. The Council on Foods therefore advises strongly against any indiscriminate dosage of mineral oil either alone or incorporated in special foods. (Jour. A.M.A., Nov. 27, 1937, p. 1814.)

OF GENERAL INTEREST

Dr. C. A. Scherer, of Duluth, has been reappointed county health officer.

* * *

Dr. A. L. Arends, of Askov, has moved to Sandstone, where he will practice medicine.

* * *

Dr. William L. Wall has opened an office in Anoka for the practice of medicine.

* * *

Dr. William Von Rohr Heise, son of Dr. and Mrs. W. F. C. Heise of Winona, has opened an office for the practice of medicine in Winona.

* * *

Dr. Arthur Neumaier, formerly on the staff of the Raiter Hospital and Clinic in Cloquet, has taken over the practice of Dr. C. P. Truog at Lindstrom.

* * *

Dr. Z. E. House and family, of Cass Lake, have returned from Florida, where they have spent some time. Dr. House will engage in private practice.

* * *

Dr. P. F. Meyer, of Faribault, has been reappointed county physician, health officer and member of the county board of health.

* * *

Dr. T. J. O'Leary, of Duluth, has been appointed president of the St. Mary's Hospital executive committee, by the governing Sister body.

* * *

Dr. J. E. Arnold, formerly of Miles City, Montana, has been appointed school doctor and village health officer of Mountain Iron.

* * *

Dr. E. J. West, who has been associated with the Arrowhead Clinic for the past ten years, has opened offices in Faribault for the general practice of medicine.

* * *

Dr. Kee Wakefield, of Minneapolis, formerly of Hutchinson, celebrated his ninety-fifth birthday on December 28.

* * *

Dr. E. V. Strand of Bayport recently returned from a trip East. Doctor Strand spent about six or seven weeks at the Polyclinic Hospital in New York.

* * *

Dr. C. T. Berger, formerly of Britt, Iowa, has opened an office in Blue Earth for the practice of medicine. Dr. Berger is a graduate of the University of Minnesota School of Medicine.

* * *

Dr. E. M. Jones, of Saint Paul, was the guest speaker at the regular meeting of the Washington County Medical Society on January 11. He spoke on "Abdominal Adhesions."

Dr. W. R. Bagley, of Duluth, who has been associated with movements for the conservation of natural resources in Minnesota and the Northwest, was endorsed for the 1937 Duluth American Legion Hall of Fame by the West Duluth Business Men's Club.

* * *

Dr. Paul A. O'Leary, of Rochester, attended the meeting of the Coöperative Clinical Group for Research in Syphilis, and a meeting of the syphilis committee of National Research council held in Washington, D. C., early in January.

* * *

Dr. Ralph T. Knight, Minneapolis, has been appointed Director of the Division of Anesthesia at the University Hospital, and since December 1 has been also supervising the Department of Anesthesia at the Charles T. Miller Hospital, Saint Paul.

* * *

Dr. H. I. Lillie, of Rochester, attended the council meeting of the American Laryngological, Rhinological and Otological Society in New York early in January. He is president-elect of the Society and will attend an eastern section meeting of the organization in Philadelphia.

* * *

Dr. Maurice B. Visscher, professor of physiology at the University of Minnesota, was the principal speaker at a meeting of the Ramsey County Medical Society held on December 27. The question of how physiological methods and ideas can be applied to the problem of a failing heart was discussed.

* * *

At a special meeting of the Wabasha County Medical Society held at Lake City on the evening of January 4, Dr. Rudolph C. Logefiel of Minneapolis delivered an illustrated address on "Gastric Diseases and the Use of the Gastroscope," with demonstrations of the modern instrument.

* * *

There are a few vacancies at present and in prospect for duty with the CCC in this military district. This medical service is rendered by Reserve Officers or by civilian physicians, who enter into contract with the Surgeon, Seventh Corps Area, who may be addressed at the Federal Building, Omaha, Nebraska.

* * *

The Interurban Academy of Medicine met in Duluth on January 19. Dr. Russell Best of Omaha, Nebraska, spoke on "Some Newer Surgical Aspects of the Biliary Tract," and motion pictures showing various phases of arterial sclerotic heart disease and changes in the stages of development were presented by Drs. Gage Clement and R. L. Nelson, both of Duluth.

* * *

The Milwaukee Sanitarium announces the appointment of Dr. Lloyd H. Ziegler as Associate Medical Di-

rector. Dr. Ziegler received his M.D. degree at the University of Minnesota, and was formerly staff consultant in neurology and psychiatry at the Mayo Clinic. He has studied clinical methods extensively in this country and abroad.

* * *

A Division of Neurosurgery in the Department of Surgery was established last summer at the University Medical School with Dr. William T. Peyton, Associate Professor of Surgery, as Director. The other staff members appointed to the Division were: Dr. J. Frank Corbett, clinical professor; Dr. A. A. Zierold, clinical professor; Dr. George R. Dunn, clinical assistant professor, and Dr. Wallace P. Ritchie, clinical assistant.

* * *

Dr. Charles K. Petter, formerly at Glen Lake Sanatorium, Oak Terrace, Minnesota, has moved to Waukegan, Illinois, where he is the Medical Director of the Lake County Tuberculosis Sanatorium Board. The Lake County Tuberculosis Sanatorium Board expects to begin the construction of a new sanatorium in the spring, and Dr. Petter will be the director of that institution.

* * *

Dr. Louis E. Jones, physician in charge at the St. Croixdale Sanatorium, passed away early in January. He was a graduate of Brown University, and received his M.D. degree at the University of Minnesota in 1924. He served his internship at St. Barnabas and University Hospitals. Dr. Jones has practiced continuously at Prescott, Wisconsin, where, in 1925, he opened the hospital which later became known as St. Croixdale Sanatorium. Dr. Jones was thirty-nine years of age, unmarried, and is survived by his mother and sister.

* * *

Dr. and Mrs. H. P. Wagener and Dr. and Mrs. Norman M. Keith, of Rochester, have returned from Europe. Dr. Wagener and Dr. Keith were delegates to the International Congress of Ophthalmology, held in Cairo, Egypt. Because of illness, Dr. Keith was obliged to remain in Amsterdam while Dr. Wagener continued the journey to Cairo, where he presented a paper by himself and Dr. Keith. Dr. Wagener also conducted a symposium on the relation of high blood pressure to the eye, and the general nature and connection between the two. He visited several eye hospitals in Egypt, where the principal problem is the treatment and prevention of trachoma.

* * *

The thirty-fourth annual Congress on Medical Education and Licensure will be held at the Palmer House, Chicago, February 14 and 15. The first day will be devoted to a report of the Council on Medical Education and Hospitals with papers covering general subjects pertaining to licensure, medical examining boards, curricula in medical schools, limitation of student enrolment. On Tuesday morning a symposium on Graduate Medical Education will be presented. At a joint session of the Council on Medical Education and Hospitals and the Federation of State Medical Boards, Tuesday afternoon, a symposium on Promulgation of Regulations Authorized by Law will be presented.

Special Convention Tour

The thought that the forthcoming A.M.A. Convention in San Francisco, June 13 to 17, is a splendid opportunity for a tour of the United States both going out and coming back, has inspired definite action. The coöperation of more than twenty-five state medical societies has made it possible to arrange a special train tour which will include the Indian Detour, the Grand Canyon, Los Angeles, Riverside and Santa Catalina Island—on the way out to San Francisco. A choice of two return routes is possible, one of which visits the cities of Portland, Seattle, Victoria and Vancouver and the scenic spots of the Canadian Rockies; the second route travels via Yellowstone National Park, Salt Lake City, Royal Gorge, Colorado Springs, and Denver.

There is an all-inclusive price for this tour which includes transportation from home town to home town, though the tour starts officially at Chicago, on Monday, June 6, from which point an American Express escort will join the group, as this travel company has been appointed transportation agent and the business details of the trip are in their hands.

Further information concerning the tour may be found elsewhere in this issue.

Sigma Xi Lecture Series

"Man and His Diet" will be the general subject of the eleventh annual lecture series by members of the University of Minnesota faculty given under the auspices of the Sigma Xi honorary scientific society this month.

The lectures will be given at 8:15 o'clock each Friday evening in Northrop Memorial Auditorium and will include the following speakers:

February 4—"The Fundamentals of Nutrition"
Dr. LeRoy S. Palmer, Professor of Agricultural Biochemistry, University Minnesota

February 11—"The Feeding of the Child"
Dr. Chester A. Stewart, Clinical Professor of Pediatrics, University of Minnesota

February 18—"Fads, Fancies and Fallacies in Adult Diets"
Dr. R. M. Wilder, Professor of Medicine and Chief of Department of Medicine, Mayo Foundation, University of Minnesota

February 25—"The Food Industries of Minnesota"
Dr. Clyde H. Bailey, Professor of Agricultural Biochemistry, University of Minnesota

Preceding each lecture a half hour's program of music will be given by the University Symphony Orchestra under the direction of Professor Abe Pepinsky.

REPORTS and ANNOUNCEMENTS

MINNESOTA HOSPITAL ASSOCIATION

The 15th Annual Convention of the Minnesota Hospital Association, together with eight allied organizations, will be held at the Nicollet Hotel in Minneapolis on May 19, 20 and 21, 1938. The allied organizations consist of the following:

Minnesota Anesthetists Association
Minnesota Dietetic Association
Minnesota Record Librarians Association
Minnesota Society of Medical Technologists
Minnesota Occupational Therapists Association
Minnesota Chapter of the American Physiotherapy Association
Minnesota District of the American Association of Medical Social Workers
Minnesota Association of Hospital, Medical and Institution Librarians

It is expected that the total attendance at this gathering will be about seven hundred and fifty.

* * *

MEDICAL BROADCAST FOR FEBRUARY

The Minnesota State Medical Association Morning Health Service.

The Minnesota State Medical Association broadcasts weekly at 9:45 o'clock every Saturday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

February 5—Infant Feeding.
February 12—Scarlet Fever.
February 19—Asthma in Children.
February 26—Gingivitis.

* * *

DOUGLAS COUNTY MEDICAL SOCIETY

The Douglas County Medical Society has elected Dr. J. C. Kyllo president for the coming year. Other officers are Dr. C. W. Mason, vice president, and Dr. S. H. Perrin, secretary-treasurer.

* * *

SCOTT-CARVER COUNTY MEDICAL SOCIETY

The Scott-Carver County Medical Society met at Mudcura Sanitarium, Shakopee, on January 11.

Dr. Willard White of Minneapolis spoke on "Treatment of the More Common Fractures." Dr. Owen Robbins of Minneapolis spoke on "Problems in Prenatal Care."

* * *

WASHINGTON COUNTY

The Washington County Medical Society held its regular monthly meeting January 11. The scientific program was given by E. Mendelssohn Jones, M.D., of St. Paul. The subject was "Abdominal Adhesions" and was very interesting, practical, and well illustrated by x-rays.

Due to the smallpox situation in the state, the Society put a notice in the newspapers advising people to be vaccinated.

* * *

WINONA COUNTY MEDICAL SOCIETY

Dr. Robert B. Tweedy, of Winona, was elected president of the Winona County Medical Society at the annual meeting. Other officers elected are Dr. H. J. Roemer, vice president; Dr. Irving W. Steiner, secretary; and Dr. L. I. Younger, treasurer.

Speakers at the meeting included Dr. Herman E. Hilleboe of Saint Paul, who talked of the work being done in this state for crippled children, and Dr. Morse J. Shapiro of Minneapolis, who spoke on heart disease among children.

* * *

CENTER FOR CONTINUATION STUDY, UNIVERSITY OF MINNESOTA

Advance Registration

Advance registrations are now being received for the winter and spring medical institutes. During the past year, medical institutes were held in: Traumatic Surgery, Obstetrics and Gynecology, Pediatrics, Internal Medicine, Roentgenologic Diagnosis, Disease of Heart, Surgical Diagnosis and Treatment, Dermatology and Syphilology and Ophthalmology and Otolaryngology. During the remainder of the scholastic year 1937-1938, institutes will be offered in Medical Diagnosis and Treatment, Traumatic Surgery, including fractures and dislocations, Endocrinology, including disorders of metabolism, Disease of Rectum and Colon and Roentgenologic Diagnosis.

Nearly 230 physicians have attended the institutes. An advance registration sufficient to guarantee a complete program as outlined above has been received. As enrollment in future institutes will be limited, physicians planning to attend should register as soon as possible. It is also helpful in planning programs to know the interests of the group in advance.

Many physicians in Minnesota and the Northwest are still unfamiliar with what the Center for Continuation Study has to offer. Under the directorship of J. N. Nolte, advanced courses of study have been offered in coöperative management, nursery teacher training, pharmacy, probation and parole problems, social welfare administration and supervision, waterworks operation, hospital administration, adult education, photography, international relations, architectural concrete, Scandinavian culture, police training, parent-teacher

leadership, traffic safety, structural engineering, educational guidance, general collegiate education, religious and ethical philosophy, trade and industrial coördination in education, technic of writing, family welfare administration and supervision, library practice and problems, Boy Scout executive leadership and medicine. For the future, a list of subjects similarly diverse is under consideration.

The Center has proved an ideal place in which "To live and learn." With accommodation for seventy-eight persons in comfortable, well-furnished rooms, every need of the postgraduate physician is satisfied under one roof. The majority of lectures are given in the Center with clinics in the University of Minnesota and affiliated hospitals. As postgraduate physicians make a personal sacrifice in giving up their practices, the Center for Continuation Study is attempting to do its part by offering full programs of practical instruction and good living at the lowest possible price.

Advance Program

Medical Diagnosis and Treatment. February 7 to 12, 1938. Lectures, clinics, demonstrations and therapeutic conferences on diseases of the gastrointestinal and respiratory tracts, the blood and blood forming organs.

Traumatic Surgery, including fractures and dislocations. March 7 to 12, 1938. Clinics will be held in the hospitals followed by lectures and conferences at the Center. Dr. Wallace H. Cole and associates. Enrollment limited to 25 students.

Endocrinology, including disorders of metabolism. April 4 to 9, 1938. Treatment of obesity, diabetes and the more common disorders of the endocrine glands, including the thyroid, uterus and ovary. Dr. J. C. McKinley and associates. Enrollment limited to 30 students.

Disease of Rectum and Colon. May 2 to 7, 1938. Clinics and demonstrations followed by lectures and conferences. Dr. Walter A. Fansler and associates. Enrollment limited to 15 students.

Roentgenologic Diagnosis. June 6 to 11, 1938. One of the popular institutes of last year. Arranged primarily for physicians who use their own apparatus for roentgenologic diagnosis. Dr. Leo G. Rigler and associates. Enrollment limited to 30 students.

Information

Write at once to J. N. Nolte, Director, Center for Continuation Study, University of Minnesota, for registration details and room reservations.

WOMAN'S AUXILIARY

Mrs. J. F. Norman, Crookston, *President*
Mrs. A. A. Passer, Olivia, *Editor*

UNDER the direction of the State President, Mrs. J. F. Norman, and the Chairman of Organization, Mrs. W. B. Roberts of Minneapolis, three medical auxiliaries were organized in the fall of 1937. On October 7, a Woman's Auxiliary for Wabasha County was organized with the following officers elected: President, Mrs. B. A. Flesche, Lake City; vice president, Mrs. J. A. Slocumb, Plainview; secretary, Mrs. G. W. Holt, Wabasha; treasurer, Mrs. D. A. Burlingame, Mazeppa. On November 18 the Winona Auxiliary was organized with the following officers: President, Mrs. C. P. Robbins, Winona; vice president, Mrs. H. W. Satterlee, Lewiston; secretary, Mrs. A. E. Meinert; treasurer, Mrs. L. J. Nilles, Rollingstone. Eighteen members joined this group. On December 9th the medical society of Clay-Becker voted to have an auxiliary and Mrs. Norman organized the auxiliary at that time with six members present. The following officers were elected: President, Mrs. O. O. Larson, Detroit Lakes; vice president, Mrs. E. K. Ingebrigtson, Moorhead; secretary-treasurer, Mrs. L. H. Flancher, Lake Park. We cordially welcome these new units and wish them a happy, active role on the honor roster. We now have twenty-four active women's auxiliaries in the state.

The midwinter board meeting of the State Medical Auxiliary was held at the Woman's Club of Minneapolis, on Friday, January 14, at 10:30 A. M. Mrs. J. F. Norman, Crookston, state president, presided at the business session, at which time a nominating committee was elected, and plans were heard for the state meeting to be held in Duluth June 29, 30, and July 1. Mrs. Augustus S. Kech of Altoona, Pennsylvania, president of the National Women's Medical Auxiliary, was the honor guest of the meeting and was the luncheon speaker to which all members of the Women's Auxiliary were invited. Reservations for the luncheon were in charge of Mrs. W. W. Moir, Minneapolis, former president of Hennepin county. Mrs. Martin Nordland of Minneapolis, a former state president, gave a tea at her home on Saturday, January 15, in honor of Mrs. Kech.

Hennepin County Auxiliary

The regular monthly meeting was held at the Hennepin County Medical Library on January 7. "Community Health Service" was discussed by Miss Laura Draper. Mrs. Edward Kelly, well known Minneapolis artist, gave a talk on "An Artist's Summer in Mexico," at the February meeting. A program of music was furnished by Mrs. H. P. McCrimmon, violinist.

Olmstead-Fillmore-Houston-Dodge Auxiliary

At the auxiliary meeting held in November, Mrs. L. M. Randall of Rochester, president, presided. Miss Priscilla Keely, social service worker at the Mayo Clinic, and Miss Jose Bosly, visiting nurse, spoke. Mrs. W. C. MacCarty of Rochester, district chairman of the Woman's Field Army for the Control of Cancer, also presented a report. Mrs. F. P. Moersch of Rochester was hostess to the auxiliary at her home on January 6. Mrs. L. M. Randall reported on activities of the state auxiliary at the American Medical Association meeting last year.

PROCEEDINGS of the MINNEAPOLIS SURGICAL SOCIETY

Stated Meeting, December 2, 1937

The President, Dr. O. W. Yoerg, in the Chair

THE OPERATIVE TREATMENT OF HYPOSPADIAS

With a Report of Three Cases in Brothers

C. D. Creevy, M.D.

Abstract

Dr. Creevy reported three cases of penoscrotal hypospadias in brothers aged six, fourteen and sixteen years; their father stated that two maternal uncles had similar deformities. The three were operated upon successfully in two stages. The first operation straightened the penis, the second constructed the urethra. A urethral fistula resulted in the oldest boy, and was closed by a third operation; in the others healing was by first intention.

The speaker discussed the various operations proposed and used for hypospadias, after pointing out that the glandular variety required no treatment, while the penile, penoscrotal and perineal varieties needed operation to relieve the functional impotence and sterility resulting from the ventral curvature of the penis and the misplacement of the external urinary meatus.

He advocated the Duplay operation for straightening the penis, and doubted whether the more elaborate proceedure of Edmunds was often required, since satisfactory straightening was secured in twelve cases, while reoperation was needed in the thirteenth. The importance of diverting the urine from the operative field during healing, either by urethrostomy or by cystostomy, was emphasized.

Of the numerous methods advocated for construction of the urethra, that of Thiersch seems most practical, while the methods of Cabot and of McIndoe are useful in certain cases. In the Thiersch operation as modified by Cecil, the new urethra is constructed from the skin of the inferior surface of the penis sutured around a sound, so that the suture line adjoins the corpus cavernosum along the roof of the urethra. The new tube is covered by a flap of penile skin pulled across it so that the external suture line lies at a distance from that in the urethra.

In two of the three cases reported, the urethra was constructed in one stage; the third required a second stage to close a fistula, but most of the other operations regularly require two stages for the construction of the urethra.

Discussion

Dr. Ivar Sivertsen: I feel as though I bring coal to Newcastle when I try to discuss a paper such as was delivered by Dr. Creevy. Most of us do not see these cases, not very many of them, at least. We probably see the penile type of hypospadias which, as Dr. Creevy says, is not of much consequence. The only treatment necessary, here, would probably be either a dilatation or even a little incision with a suture of the mucous membrane to the glans penis.

I have seen only one case of the penile type and it had a large roof of mucous membrane which it was possible to dissect away from the side of the penis and bring over a catheter. We obtained in this way a fairly good result except that a small fistula resulted which was later cured.

As to the time of operation in these cases, it seems to me that the best time to operate is before puberty. Some recommend that they be operated upon between the sixth and the tenth year. I don't know that Dr. Creevy mentioned that it makes any difference. Certainly, in the penile type of case where it is necessary to straighten the penis you have to separate the corpora cavernosa from around the urethra. Most men, I think, bring the penis up on the abdominal wall after they have made such a dissection of the corpora cavernosa and then probably do a cystostomy. I don't know which is the better procedure. Dr. Creevy certainly is a master in this work and it is not for me to say. The only cases we have seen we did do that very thing. I have not had any experience with the perineal type but I am sure that it is a very difficult procedure.

There was one operation, however, the Bucknell operation, that he spoke about, that has been modified by an Englishman where they used the prepuce of the penis and split that and brought it down upon the surface of the scrotum after making an incision on the scrotum and using the mucous surface of the prepuce as the floor of the urethra. To me, this appears to be a very satisfactory way. After doing this they wait some weeks and then do a modified Bucknell operation and apparently get good results. I don't know whether Dr. Creevy has seen this operation, the so-called Winsberry-White modification of the Bucknell operation. There, you will get tissue that is without hair and it can be brought up against the roof of the urethra.

Most men feel that unless you have a very definite reason for performing these operations, as in the so-called perineal hypospadias, they had better be left alone unless they can be done by an expert. I don't know but what I would leave them alone unless I could send them to Dr. Creevy. The penile type, of course, can be improved by the so-called Winsberry-White modification of the Bucknell operation.

I certainly want to congratulate Dr. Creevy on his very beautiful demonstration of this procedure, and I am very happy to have had the privilege of listening to his paper.

Dr. Kenneth Bulkley: I would like to know what Dr. Creevy thinks about the most suitable age for the operative procedure on these cases?

Dr. C. D. Creevy: Dr. Sivertsen mentioned an important point that I neglected to speak about in connection with the straightening of the penis. In the extreme degrees of deformity the intact part of the urethra just behind the hypospadiac meatus may also be shortened and in this particular variety it is very helpful to dissect the urethra completely free from the corpora cavernosa. One then circumscribes the meatus by a circular skin incision, lets the urethra re-

tract beneath the skin, and makes a buttonhole in the skin further back for the meatus.

As for the best age for operation, it is usually said that the penis ought to be straightened whenever the patient is first seen, and that the construction of the urethra ought to be put off until the penis has become large enough to make the operation a simple matter. Early correction of the deformity is urged because, as time goes on, the ventral surface of the corpora cavernosa becomes shortened and the deformity may be permanent. However, I have operated on a man of twenty-five, and didn't find it any more difficult to straighten the penis than in very young children. As a matter of fact, because of the size of the structures, it was considerably easier, so that I am not sure that there is any particular advantage in straightening the penis early in life.

HEPATIC CIRRHOSIS

Talma-Drummond-Morrison Operation

R. R. Cranmer, M.D.

Most classifications of liver cirrhosis are not wholly satisfactory. The following classification is based on the condition of the liver and the presence or absence of certain findings as ascites, portal vein obstruction, jaundice, and enlargement of the spleen.

1. Atrophic cirrhosis, hobnail liver, Laennec's cirrhosis, alcoholic cirrhosis.
   In this type the liver is rough and nodular, tends to be smaller than normal, there is marked portal obstruction with ascites and enlarged spleen, and no jaundice.
2. Obstructive biliary cirrhosis.
   Liver enlarged, smooth or granular. Jaundice present with clay colored stools. Usually no ascites but spleen may be enlarged.
3. Hypertrophic or Hanot's cirrhosis.
   Liver large and smooth. Jaundice but bile stained stools. No ascites, splenic enlargement.
4. Tuberculous and syphilitic cirrhosis.
   In addition Banti's disease (splenic anemia) is considered by some to be in reality another form of this condition in which the blood changes are marked, due, in large part, to massive hemorrhages.

Many things have been blamed as the cause of liver cirrhosis. Chronic alcoholism seems to be the thing most generally considered responsible. Arsenic and copper have frequently been mentioned. About 50 per cent of patients with cirrhosis give the history of alcoholic addiction. Perhaps, many of the remaining 50 per cent are users of it but do not admit it. Postmortems done on 134 chronic alcoholics in one large institution showed cirrhosis in only six.

Splenomegaly and ascites, with or without jaundice, depending upon the type, are the outstanding features in the advanced cases. Men present this condition about four times as frequently as women.

Conditions simulating liver cirrhosis and requiring differential diagnosis are: abdominal carcinoma, cardiac disease, tuberculous peritonitis, and, in women, large ovarian cysts.

The ascites in cirrhosis has been generally considered to be due to portal obstruction within the liver with resulting back pressure and accumulation of a transudate in the peritoneal cavity.

Others believe that following this the ascites is increased by congestion-excited endothelial cells pouring out an exudate.

Many of these cases have a coexisting myocardial insufficiency which may also be an etiological factor.

Toxins generated in the intestinal tract and spleen, when not removed by the liver, are thought by some to be the cause of the endothelial stimulation.

If the ascites is due to portal obstruction and also, in part, to the presence of toxins in the circulation causing stimulation of the endothelial cells of the peritoneum, any operation looking toward a cure should be one that reduces the obstruction and reduces the toxemia. If the toxins have their origin in the spleen its removal or the establishing of collateral circulation through adhesions produced between it and its contact peritoneum should be logical treatment.

The long continued portal obstruction results, in many cases, in dilatation of anastomosing venous systems uniting the portal with general circulation.

These anastomoses occur:

1. Between the coronary veins of the stomach and lower esophageal veins, the later opening into the right azygos and intercostals.
2. Between the branches of the inferior mesenteric vein, the superior hemorrhoidal and the branches of the internal iliac veins, the middle hemorrhoidal.
3. The veins of Retzius which originate in the walls of the intestines, and through a small trunk open into the ascending vena cava.
4. Anastomosis of veins about the umbilicus (caput medusæ).

Surgical procedures are aimed at:

1. Establishing collateral circulation
2. Reducing the portal bed
3. Draining the ascitic fluid.

Omentopexy suggested first by Talma and carried out by many others, including Drummond and Morrison, has been a popular procedure. This, in conjunction with the production of adhesions between the liver and peritoneum and between the spleen and peritoneum, constitutes the more modern operation known as the Talma-Drummond-Morrison operation.

Operations to reduce the portal bed are splenectomy and enterectomy. The last named operation described by M. K. Fuller of Chicago and her associates, in the *Surgery, Gynecology and Obstetrics* of September, 1937, consists of removal of several feet of small bowel. Basis for enterectomy in this condition is the hypothesis that obliteration of part of the portal bed by resection

of several feet of small intestine might decrease the returning venous blood to an amount which might pass through the cirrhosed liver, thereby decreasing the pressure in the portal veins and capillaries, and diminishing the transudation from the portal system into the peritoneal cavity.

Operations for the drainage of the ascitic fluid are, of course, palliative in nature.

Paracentesis continues to be the most practical of these. Eck's fistula, while ideal theoretically, is of no practical value because of the technical difficulties of the operation and high mortality associated with it.

Spheno-peritoneal anastomosis has been successfully done with good results in a few cases.

Case Report

The patient, a male, aged fifty-five, entered the hospital on March 1, 1935. His chief complaint was distention of abdomen, anorexia, nausea, general weakness, loss of weight, and pains in calves of legs.

Family history was essentially negative, no member of the family having had a similar condition.

The patient had the usual diseases of childhood. He had pneumonia two years previous to his admission. There was no history of scarlet fever or rheumatic fever. Genito-urinary history was negative except for gonorrhea fifteen years previous. He had been addicted to drinking for a period of thirty years and during the last twenty years averaged a pint of hard liquor daily. He dates the onset of his illness July, 1934, when he first became faint and dizzy upon exertion. Following this there was a loss of appetite and weight. He, then, noticed a distention of the abdomen which was progressive. His weakness increased until six weeks previous to his admission it became necessary for him to stop his work. He noticed that the urine was dark and that the stools were occasionally light yellow. There was no apparent jaundice.

Physical examination revealed that the patient was a moderately well developed man who did not appear acutely ill. There was no appearance of jaundice. Heart and lungs were normal. Abdomen was considerably distended. It was impossible to palpate the liver or spleen satisfactorily. There was no abdominal tenderness and no palpable masses. There was no edema of ankles. Varicosities of abdominal walls especially noticeable over right side extending into the chest. Blood examination showed hemoglobin 65 per cent; 3,200,000 red blood cells and 5,700 white blood cells per cu. mm.; pmns. 74.8 per cent, lymphocytes 25 per cent. Urinalysis revealed 1015 specific gravity; urobilin, 1 plus; urobilinogen, faint trace; occasional hyalin and granular casts; 2 to 4 pus cells; and no red blood cells. Quantitation urobilinogen test showed .44 mg. in twenty-four hours. Icteric index was 13. Urea nitrogen 7 mg. per 100 c.c. Galactose liver function test showed a total urinary output of 79 per cent of sugar in five hours.

Diagnosis: Cirrhosis of liver with ascites.

The patient remained in the hospital four weeks before operation, during which time abdominal paracentesis was done several times. The amounts of fluid removed ranging from 1,500 to 4,000 c.c. Following paracentesis, the lower edge of the liver could be felt for a distance of three fingers breadth below the costal margin. The spleen was easily palpable. The fluid was amber in color. His condition after a month's rest seemed slightly improved although there was no diminution in the amount of ascitic fluid accumulating. On May 2, following a paracentesis a Talma-Drummond-Morrison operation was performed under general anesthesia. The abdomen was opened through an upper left rectus incision and about a liter and a half of straw colored fluid was aspirated. The liver was enlarged to three fingers below the costal margin. Its edge was sharp and the surface was finely granular. The spleen was enlarged about three times the normal size. The upper surface of the liver was roughened by dry gauze spread over the fingers. The under surface of diaphragm was treated in a similar way. A similar procedure was carried out on the outer surface of the spleen and its contacting peritoneum. The anterior surface of the omentum was sacrificed, as was, also, the parietal peritoneum covering the anterior wall, for a distance of about seven centimeters lateral to the wound edges. The entire anterior surface of the omentum was sutured to the anterior abdominal wall and the wound was closed. The patient left the hospital June 4 with a small amount of ascitic fluid present in the abdomen. There was no paracentesis done following operation. Two months after his discharge very little fluid was present in the abdominal cavity and in four months time it had entirely disappeared. He returned to work about six months after the operation.

Discussion

Dr. E. A. Regnier: I think Dr. Cranmer is to be congratulated in presenting a patient with cirrhosis who is apparently in such good health. Our results in treatment of ascites associated with cirrhosis by the Talma-Morrison operation have not been good; in fact, they have been so discouraging that in the event of an apparent recovery one always is inclined to doubt that he was dealing with a true cirrhosis. The cause of the ascites is still very debatable. If it is due to a toxin the progress of the disease is not affected by any surgical operation. The case presented here this evening has obviously been completely relieved of ascites, which has brought him great bodily comfort and this good result certainly justifies the procedure. My own experience in this field has been very limited. I have one case relieved of ascites five years after operation. This was a case of cirrhosis associated with Banti's disease in a young girl, nine years old, in whom a splenectomy was done five years ago. She has remained well following splenectomy and omentopexy for the relief of ascites. One must not lose site of the fact that we are not treating cirrhosis but are operating to relieve a very annoying symptom, namely ascites, and the progress of the disease is not altered by this procedure.

Dr. Ralph Knight: I would like to ask Dr. Cranmer if the abdominal veins are now distended?

Dr. Kenneth Bulkley: Has the size of the liver changed any?

Dr. R. R. Cranmer: No, the veins are not distended. I would like to say that one of the best papers I have ever read in connection with this type of thing is one written by Dr. Earl Hendrickson. He reviewed all the literature very thoroughly and it was published last year in the *Archives of Surgery*. I do not believe you can see any dilated veins here now. Here is the incision, a left rectus incision, and here especially is where he had quite a few dilated veins, over the chest and right side of the abdomen.

Replying to Dr. Bulkley's question, we had him on the table a couple of days ago and we could feel the edge of the liver at least two fingers below the costal margin.

In the Talma-Morrison operation the idea is to produce collateral circulation by adhesions between the liver and peritoneum on the under-surface of the dia-

phragm and between the spleen and peritoneum and if good collateral circulation results in these locations and between the omentum and the abdominal wall, any dilated veins on surface should disappear.

Dr. C. E. Merkert: I would like to ask whether the formation of adhesions in this operation actually does drain the abdominal cavity by forming new veins or is it through the lymphatics that are connected as in the Kondoleon operation for elephantiasis of the leg?

Dr. R. R. Cranmer: I believe it is in the new veins.

OBSCURE RETROPERITONEAL ABSCESS

Verne Cabot, M.D.

Miss A. O., a school teacher, unmarried and thirty-one years of age, entered the hospital September 11, 1936, with a history of illness for the past five weeks consisting of weakness, abdominal distress and fever, associated with severe anorexia but without nausea or vomiting. She was a rather small woman in moderate state of nutrition though showing the effects of a prolonged and severe illness.

Her previous history was of special import in that fourteen years ago she had undergone surgical intervention for appendiceal disease with abscess which was drained. Her postoperative period was very stormy and during her ninth postoperative week she was again submitted to abdominal incision for secondary abscess and again in her tenth week a deep abscess in the right lower lumbar region was also evacuated. From these surgical procedures she apparently convalesced until her eleventh week, when she suffered a siege of pneumonia, from all of which she recovered and was discharged from the hospital after fifteen weeks. She states that her health has not been robust since this period. She has tired easily and has been subject to backache for which she had been treated under the diagnosis of spinal arthritis (lumbar). The school-year of 1935-1936 she did not teach because of poor general condition. The summer of 1936 was spent in resting until in mid July when she became acutely ill complaining of indefinite abdominal discomfort with weakness and fever which had persisted to the time of our first seeing her when she was admitted to the hospital.

On admission, examinations showed a moderately tender lower right abdomen with greatest intensity along the anterior margin of right ilium downwards from the superior iliac spine for a distance of about 10 cm. and extending mesially for about 2 cm. There was no appreciable muscular rigidly. Other examinations of the abdomen and pelvis were essentially normal. There was slight pain on complete extension of the right thigh, which she attributed to the position she had assumed during her illness and to her chronic arthritis. There was no undue tension or tenderness over her lumbar areas. Her weight had dropped from 116 to 92 pounds the past year.

Temperature 102.6; pulse 78; respirations 18.

Blood studies: Hgb. 76 per cent; r.b.c. 4,250,000; w.b.c. 18,400. Repeated w.b.c. ranged from 12,000 to 22,000 with an average of 80 per cent pmns. Numerous urinalyses were at all times normal. The blood Wassermann and Mantoux tests were negative.

Roentgen studies of chest and urinary tract with pyelograms revealed no abnormalities. Gastrointestinal studies showed normal findings except for a very low lying cecum somewhat fixed and tender. The appendix was not visualized. Detailed x-ray studies of skeletal systems of chest, lumbar and pelvic regions were negative for osseous changes though there was a slight scoliosis of the lumbar region and a fogginess of the lateral margin of the right psoas magnus, especially in its lower portion, which was explained as being a result of her previous lumbar suppurative processes both intra- and retroperitoneal.

An attempt was made to obtain records of her earlier operations but the records of both hospital and surgeon had been destroyed. We felt these records were of great importance, thinking that possibly the appendix had not been removed.

Consequently on her sixth day in the hospital she was submitted to abdominal exploration, at which time a few omental adhesions attached to areas of previous drainage sites were separated. The cecum was low and somewhat fixed. The appendix had been removed. There was a definite irregular enlargement of the right psoas muscle with increased tension, especially in its lower or iliac portion. The wound was closed and walled off. Following this, aspiration of the concavity of the right ilium extraperitoneally was attempted without success. Incision was then made just mesial and downwards from the right superior iliac spine. It being carried inwards outside the peritoneal cavity until the mass was entered and drained of heavy yellow pus. Cultures taken showed subsequent growths of staphylococcus only. Her convalescence was definite though her draining sinus persisted despite rest, high protein diet, vitamins, autogenous vaccines, etc. She left the hospital at the end of her second month much improved in health, but with the sinus draining steadily though somewhat less. She continued to drain and was again admitted to the hospital January 11, 1937. Repeated x-ray studies prior to her leaving the hospital and following readmission showed no further abnormalities. Biopsy of the sinus tract showed chronic inflammatory changes with occasional giant cells.

To ascertain the exact location and extent of the abscess and persisting sinus, the tract was injected with lipiodol as shown by the films, following which there was a noticeable diminution of discharge as well as a change from heavy pus to a more serous type. The improvement was so noticeable that four days later lipiodol was again injected. Then sodium ricinoleate 5 per cent and lastly 5 per cent sodium psylliate were injected. Her improvement was so marked that she was discharged three weeks following the first injection, with her sinus rapidly granulating in, which it continued to do until shortly it closed over without further recurrence. In all she received nine injections, three of iodized oil and six of sclerosing solutions. Her general health has been excellent to date as evidenced by her normal temperature readings and weight gain to normal.

Repeated x-ray studies of the involved areas have been taken, the last one of which was taken September 27, 1937.

The diagnosis in this case was: Retroperitoneal abscess involving right psoas and iliac muscles, origin undetermined.

Discussion

Dr. Daniel A. MacDonald: In studying case histories of retroperitoneal abscess one is impressed with the difficulty of diagnosis and the obscurity of the cause of the abscess. The difficulty of diagnosis is admitted by the fact that on an average about five weeks elapses before a diagnosis is made.

There may be no tenderness in the subcostal angle. Redness and swelling in the lumbar region occur late because the inflammatory mass lies beneath thick muscles and strong fascial planes. Pain may be absent because sensory nerve endings are absent, and, with practically no restriction to the expanse of exudate,

tension is lacking till late. There is no irritation or displacement of organs which would help in diagnosis. The kidney varies so much in its mobility that its change of position may be of little significance.

The source of infection in retroperitoneal abscess a great many times comes from intra-abdominal organs. The source of infection in intra-peritoneal subphrenic abscess usually comes from a diseased intra-abdominal organ. Subphrenic abscess is more common than retroperitoneal abscess because when these intra-abdominal organs do perforate, as a rule they perforate into the free peritoneal space rather than retroperitoneally. The reason for this is because most organs of the abdomen have a more perfect fusion of their posterior peritoneum, or, in other words, a more perfect mesentery. Therefore, we would expect a retroperitoneal abscess to come from a perforation of the colon, posterior duodenal wall, retrocolic appendix, abscess of the head of the pancreas, etc., if the source of infection is from an intra-abdominal organ, because with these organs we do not have as perfect a fusion of their posterior peritoneum.

The peritoneum is more sensitive to irritation and subphrenic abscess develops more quickly unless the great protective powers of the peritoneum destroy the infection, so with less irritation and symptoms developing more slowly the cause of retroperitoneal abscess is more obscure. There may be no urinary findings if a perinephritic abscess originates from the cortical portion of the kidney.

I feel that Dr. Cabot showed considerable ingenuity in treating his case with the sclerosing fluid and one would feel she would remain well after this length of time, with no recanalizing of the sinus or evidence of the infection.

X-RAY TREATMENT OF ACUTE INFECTIONS

M. B. Hanson, M.D. (by invitation).

Roentgen-ray therapy has proven itself a very valuable agent to the surgeon in the treatment of acute infections. With the publicity and propaganda given cancer and other malignancies and the treatment of x-ray, I think we have lost sight of the beneficial effects of x-ray therapy in other conditions. X-rays, shortly after their discovery, in 1895, were used in the treatment of cutaneous infections with varying results. This was due to incomplete knowledge of the output of the machines, filters, and also the biological reaction of the tissues. Since that period there has been a tremendous advance in the application and control of x-ray therapy, selection of cases, and comparative appreciation of results. It is the clinical evaluation of these results which gives us a rationale for this type of therapy.

X-rays *per se* are not bactericidal in vitro with the doses administered to a patient. However, when these same doses are administered to an infected area there is a complex biological reaction which not only is bactericidal but stimulates tissue repair. There have been many explanations of these processes but today the details of this reaction (which I shall not discuss) are still debatable.

Both acute and chronic infections are amenable to x-ray therapy. Acute infections, with their relative large number of leukocytes and small amount of connective tissue, however, respond more favorably. It is very important that the infected area be treated as early as possible, preferably within eight to twelve hours after the onset. It is within this period that many of these infections may be aborted. Baensch, in reporting over a hundred cases of furuncles of the face, was able to abort a large number and this mortality was less than 2 per cent as compared to a similar series conducted at the same time without roentgen therapy, which had a mortality of 10 per cent.

The clinical response to x-ray consists of:

1. Relief of pain, which occurs quite rapidly, usually within eight hours after treatment.
2. Lower temperature, which in many conditions such as erysipelas, boils, felons, lymphangitis, postoperative parotitis and acute bursitis, may return to normal within twelve to twenty-four hours.
3. Lessened toxicity.
4. Fairly rapid regression of the inflammation, if treated early, or, if treated later, a definite tendency to localize the infection with a resulting decrease of disability and number of hospital days.

In conclusion:

1. The surgeons have a valuable method to add to their armamentarium in the treatment of acute and chronic infections.
2. The earlier an infection is treated the more favorable the results.
3. Roentgen therapy is now well controlled without danger and discomfort to the patient.

Discussion

Dr. Kenneth Bulkley: This paper of Dr. Hanson's has been of interest. I do not believe he has quite covered his field. He spoke of the rapid subsidence of pain. In the fall of 1936 I had the misfortune to contract a tularemia. My primary focus was in my right hand and subsequent to leaving the hospital I developed a large mass of glands in the right side of my neck and right axilla. I would say that for a period of six weeks there was not a night that I did not wake up about one o'clock with a steady ache in my neck and armpit. Previous to this time I had not been cognizant of the value of x-ray therapy in tularemia. Dr. Hanson, however, very kindly gave me two exposures, using, I believe, one-third of an erythema dose on a 200,000 volt machine. The first dose was given one morning at about nine o'clock. Thereafter I slept without pain and had no further difficulty with my glands. They had subsided fully 50 per cent within a week and a week after the second dose were entirely gone. I wonder if anyone has any knowledge as to the early treatment of a fresh case of tularemia by x-ray therapy? It would be interesting to see what would happen if such a case received adequate therapy, certainly over the initial lesion, probably over the spleen, and possibly also over the lungs.

Dr. Ivar Sivertsen: I would like to ask Dr. Hanson if he would use serum in cases of erysipelas and also of gas gangrene plus x-ray treatment.

Dr. M. B. Hanson: In reply to Dr. Bulkley, I realize that this large field has only been scratched in this brief paper. There are so many acute infections which are being treated with x-ray therapy and with good

results, that I tried to cover only a few of the most common surgical problems in the ten minutes allotted. X-ray has been used with satisfactory results in the treatment of enlarged nodes associated with tularemia. In these cases there has been a fairly rapid disappearance of pain and a slower regression of the size of the nodes.

Dr. Sivertsen's question concerning the use of serum in erysipelas, x-ray or ultra-violet lamp is sufficient for treatment in the average case of erysipelas. However, when the lesion is very extensive, serum may be used as an added weapon.

PRIMARY LOBECTOMY FOR BRONCHIECTASIS

Thos. J. Kinsella, M.D., F.A.C.S.

Abstract

The four patients to be presented this evening were chosen because they illustrate a number of points in the surgical treatment of bronchiectasis. Bronchiectasis is essentially a condition, not a primary disease. It may be congenital in origin or occur secondary to a number of conditions such as intrabronchial foreign bodies, pulmonary abscess, bronchial tumor, tuberculosis and a number of other processes in which the association of infection with bronchial stenosis or some other interference with bronchial drainage leads to weakening of the bronchial wall, dilatation and the production and retention of various amounts of secretion in the involved area. The condition is essentially a chronic one whose early course is frequently mild and characterized by periods of complete or relative absense of symptoms. Intercurrent episodes of pneumonitis or pneumonia are not uncommon. The early symptoms are those of a recurrent chronic bronchitis, but later there occurs more constant cough with expectoration of varying amounts of purulent material which becomes foul if there is retention of secretion. Pulmonary hemorrhage of varying degrees of severity occurs in at least one-half of the patients. In the later stages, cyanosis of the lips, cheeks, and digits is a frequent occurrence and clubbing of the fingers and watch crystal nails are often seen. The condition is compatible with life for long periods of time. In the early stages the cough is more of a nuisance than a handicap, but in the later stages the profuse expectoration, particularly if foul, becomes a serious handicap, interfering with useful work and more or less ostracizing the patient from his associates. Pulmonary hemorrhage and the attacks of pneumonitis may seriously endanger the patient's life.

Conservative measures of treatment, even combined with treatment for sinus infection, postural drainage, bronchoscopic aspiration or lavage, etc., may temporarily relieve symptoms but do not cure the condition. Removal of intrabronchial foreign bodies or tumors or strictures, or the aspiration and drainage of associated abscess, may improve the condition but do not eliminate the damage that has already been done.

The rapid development of thoracic surgery in the past fifteen or twenty years has now made it possible to relieve a number of these patients, if the condition has not progressed too far. Thanks to the pioneering work of Brumm, Shenstone and others, it is now possible surgically to remove the involved lobe or lobes in certain selected patients without the appalling mortality which attended all earlier attempts to treat this condition. The following four patients will be used to illustrate these points:

The first patient is a little boy upon whom I performed a left lower lobe lobectomy on April 23, 1937, when he was three years ten and one-half months of age. He gave a history of pertussis at the age of one, an attack of pneumonia or pneumonitis of a chronic type in October, 1935, with high fever, sweats, severe cough, choking spells and cyanosis and the expectoration of thick, brownish green sputum with foul odor. In September of 1936 he had cough and small hemoptysis on two occasions. He had been subject to repeated colds, showed evidence of sinus disease and presented clubbed fingers and watch crystal nails. His tonsils and adenoids had been removed in November, 1936, when sinus drainage had also been established. Bronchoscopy revealed cylindrical and saccular bronchiectasis of the left lower lobe with associated atelectasis. The upper lobe and the contralateral lung were apparently free of involvement. The chest was opened by a posterior incision along the seventh interspace and a wide segment of the seventh rib excised and the sixth and eighth ribs sectioned near their angles. The pleural cavity was then opened and found to be almost entirely free of adhesions. The upper lobe was soft and pink, crepitant throughout, and collapsed readily. The lower lobe was purplish blue in color, firm, indurated and somewhat nodular, and collapsed very little when the chest was opened. The inferior pulmonary ligament was sectioned, the interlobar fissure freed and the pedicle of the lower lobe mobilized. A lobectomy tourniquet was placed around this pedicle, which was then transfixed and doubly ligated with braided silk. A second tourniquet was placed distal to the first and the involved lobe resected between the two tourniquets. All protruding vessels and bronchi were then sutured individually, and an attempt was made to close the exposed stump by approximating the adjoining pleural surfaces, but this could only be done incompletely. A second mass ligature was placed in the groove occupied by the tourniquet as it was removed. The chest wound was then closed tightly, leaving three mushroom catheters through stab wounds in the chest wall, and constant negative pressure of approximately 15 to 18 mm. of mercury applied. The postoperative condition was at all times satisfactory. Apparently the upper lobe expanded to fill the whole chest as breath sounds soon became evident throughout and we were left with only a small empyema pocket posteriorly into which a bronchial fistula opened as the stump sloughed off at the end of twelve days. We have been unable to determine just exactly what has happened to the upper lobe on this side. We will note from the x-rays that there is a

diffuse shadow occupying this side of the chest, although there are breath sounds present and the percussion note is not markedly altered. Whether this represents thickening of the pleura or whether there has been a thrombosis of the pulmonary vessels on this side or a permanent atelectasis of this lung we have been unable to determine. This boy ran a slight febrile course for several weeks but eventually his temperature returned to normal. He still has a very slight cough, but apparently is raising nothing, although at times, from the sound of his cough, one would suspect that there is a little secretion present. I believe that he still has a small bronchial fistula leading into a very small pocket posteriorly near the hilum. Deep fistulæ of this type eventually close spontaneously and should not be disturbed. His general condition is good. He apparently is developing symmetrically, is gaining weight, running no fever, and is running a normal leukocyte and differential count.

The second patient, a boy eight years three and one-half months old, was subjected to a right lower lobe lobectomy June 7, 1937. He gave a history of a pneumonia at the age of two years, frequent colds, and a productive cough at times. In December, 1933, he apparently had an acute mononucleosis with a leukocyte count of 94,000, with 90 per cent lymphocytes. In January, 1937, he had another attack of pneumonia or pneumonitis, with a temperature of 102.8, at which time he became delirious. Examination revealed bilateral ethmoid and maxillary sinusitis, and bronchoscopic examination revealed a bilateral lower lobe bronchiectasis, much more extensive on the right side. The tonsils and adenoids were removed and sinus windows established on February 18, 1937. Cough and expectoration were present but only very mild finger changes. Because of the extensive involvement in the atelectatic right lower lobe, it was decided to do a right lower lobe lobectomy on this side in spite of the bilateral disease. This was performed June 7, 1937, under cyclopropane anesthesia and was well tolerated. The technic was essentially the same as described previously except that we found the pleural cavity obliterated by filmy adhesions which were easily dissected away. The post-operative convalescence was relatively uneventful. The temperature reached a maximum of 103 on the eleventh post-operative day, but was down to normal at the end of thirty days. The remaining lung expanded rapidly to fill the pleural cavity. No empyema pocket developed and to our knowledge no bronchial fistula resulted. An obliterated pleural cavity before operation undoubtedly reduces the chance of an extensive post-operative empyema. He has no cough or expectoration now. We plan no surgical attack on the left lower lobe unless future progression of the disease renders it imperative.

The third patient is a man thirty-three years of age, who had no pulmonary trouble until 1927, when, soon after the extraction of all his teeth under general anesthesia, he began to cough and expectorate moderate amounts of purulent sputum, which at times was quite foul. Symptoms continued more or less the same until 1930, when he was bronchoscoped by Dr. Vinson at the Mayo Clinic and a tooth removed from the right lower lobe. Following this he improved somewhat, but continued to have cough and expectoration, frequent colds which always extended to his chest, and was continually below par and unable to work. Bronchoscopy revealed pus from the right lower lobe bronchus, and bronchography an atelectatic right lower lobe with cylindrical bronchiectasis. On September 3, 1937, under intratracheal cyclopropane anesthesia administered by Dr. Ralph Knight, the right pleural cavity was opened through a posterior incision, the adhesions about the lower and middle lobes dissected free, and the atelectatic lower lobe resected. The chest was closed tightly and two catheters inserted through stab wounds and continuous negative pressure applied. Obstructive atelectasis of the right upper and middle lobes followed, but cleared within forty-eight hours. A small empyema pocket developed posteriorly about the lung stump as the bronchus opened at the end of two weeks. This was opened widely and packed, and is healing satisfactorily. He now has practically no sputum, is up and about, and in good condition generally.

The last patient is a physician thirty-nine years of age who has coughed as long as he can remember, always raising varying amounts of sputum which was never foul. Severe pulmonary hemorrhage occurred on numerous occasions. In 1917, following an unusually severe hemorrhage of about 500 c.c., pulmonary tuberculosis was suspected and a left pneumothorax induced and continued until 1920 without controlling either the hemorrhage or sputum. The diagnosis of tuberculosis was never confirmed. Cough and expectoration of purulent sputum in amounts from 4 to 60 c.c. continued with frequent blood-streaked sputum, and occasional frank pulmonary hemorrhage amounting to 300 c.c. in 1930 and again in 1935. In April, 1937, he developed an acute pneumonitis at the left base. Blood-streaked sputum appeared again in July, 1937. Examination revealed elevation of the left diaphragm and displacement of the heart and mediastinum to the left from atelectasis of the lower lobe. Bronchoscopy revealed pus from the left lower lobe bronchus, which was definitely stenosed. There was no evidence of foreign body. Iodized oil visualized a cylindrical bronchiectasis of the left lower lobe.

Through a posterior incision a left lower lobectomy was performed under intratracheal cyclopropane on September 2, 1937. The pleural cavity was completely obliterated by very dense scar tissue containing numerous large blood vessels. The whole operation was very difficult, requiring nearly seven hours of tedious dissection to complete it. Closure was made as in the previous cases. The post-operative convalescence was relatively smooth except for a small area of bronchopneumonia at the right base. A very small abscess about the bronchial stump drained through the bronchus. The wound is completely healed. He now has almost no

cough or expectoration, has gained weight, feels fine, and plans to resume practice very soon.

A more complete report of these and other cases will be made later.

Discussion

Dr. Ralph Knight: Dr. Kinsella is to be congratulated upon his meticulous, exact work and beautiful results. It has been a pleasure to give some of these anesthesias for him.

Recently I saw Dr. Shenstone of Toronto perform chest operations. For his lobectomies two types of anesthesia were employed by his anesthetist, Dr. Harry Shields. On a certain morning, the first case, a woman, was given spinal anesthesia. The dose and the dilution of the novocaine were so calculated that the patient had anesthesia up to the clavicle, but the intercostal muscles were not paralyzed and the patient was able to cough and clear out the secretions, which were rather copious on account of the bronchiectasis for which she was being operated. The second case was a large man and Dr. Shields chose for him general anesthesia by cyclopropane, administered through an intratracheal tube. The surgeon seemed to like the spinal anesthesia fully as well as the other. While spinal anesthesia is very fine, I feel that in these cases the anesthetist has better control over the whole situation if he employs an intratracheal tube. The expansion and ventilation of the lungs and the removal of secretions are accomplished at will.

Our ideas are changing in regard to the use of the intratracheal tube even in rather small children. We find that they can be given a tube very well. If a rather small tube must be used it helps very much to mix about 50 per cent helium with the oxygen. This reduces the specific gravity of the gas mixture very materially and it passes through the small tube with much less resistance than does oxygen alone. Even after 20 per cent or 25 per cent of cyclopropane is added to this mixture to produce anesthesia the percentage of oxygen still remains very high and oxygenation is ample. When an intrabronchial tube is used for the administration of cyclopropane through the good lung, during the removal of the entire opposite lung for bronchiectasis, the tube is necessarily smaller than a tracheal tube and the helium mixture is a great help. The same is true in giving an anesthetic to an asthmatic patient.

It was not necessary to use helium for either of these lobectomy operations on adults for Dr. Kinsella. They both took the cyclopropane very well through an intratracheal tube, their respiration was shallow and quiet throughout and their color very good. Secretions were sucked out at frequent intervals.

I have noticed that in all of these major chest cases there is a tendency to the occurrence of post-operative paresthesias and partial paralysis of the arm on the same side. The position on the table and the need of the operating team for room probably causes the arm to become hyperextended, thus stretching the brachial plexus. The effect is upon the radical and median nerves, not upon the ulnar. Recovery is rather slow but is practically always complete. Every effort should be made to avoid this complication.

Dr. Nathaniel Lufkin (by invitation): As you know, the presence or absence of bronchiectasis is not as a rule difficult to determine at the autopsy table. In most cases where death has resulted from bronchiectasis or its complications, dilatations of the bronchi are very obvious. These are most frequent toward the periphery of the lung and frequently the dilatations have become converted into large abscesses.

The specimens removed by Dr. Kinsella presented a picture quite unlike that customarily seen in the post-mortem specimen. (Here is shown a lantern slide made from the photograph of one of Dr. Kinsella's specimens. Both the external and cut surfaces of the lung are shown.) This is the specimen removed from the first youngster. As you will note, it is much smaller than normal. The entire specimen is not much more than two inches long. This, I believe, is the result of atelectasis, part of which probably occurred during the operation. On the cut surfaces you will note the entire absence of dilated bronchi or abscess cavities. Instead, you have a very striking picture of very white, greatly thickened bronchi standing out in high contrast against the surrounding hemorrhagic and atelectatic lung tissue. This thickening is caused by two fundamental changes. First, there is a tremendous hypertrophy of the bronchial mucosa. Not only the membrane but the individual cells of the membrane are hypertrophic. Fairly frequently the mucosa is so redundant that it might be described as polyoid. Not infrequently a section of bronchus bears a superficial resemblance to a section of fallopian tube because the mucous membrane is thrown into so many irregular folds. The other change which contributes to thickening of the bronchi is bronchial and peribronchial fibrosis and infiltration. The connective tissues surrounding the mucous membrane are densely infiltrated with leukocytes, largely plasma cells and lymphocytes. There is a severe degree of accompanying fibrosis which extends far beyond the muscular coats of the bronchi and to varying degrees involves the air-bearing pulmonary tissue adjacent. Almost invariably the bronchial musculature is altered by this chronic inflammatory process. Frequently, it can hardly be made out. In these places it has evidently been almost completely destroyed.

All four of the specimens removed by Dr. Kinsella showed these changes as the outstanding alterations. There were, of course, minor differences between the specimens and there were also other alterations which were probably not part of the fundamental process. Only one showed cavities. This was the case in which symptoms had lasted for thirty or more years. It is my feeling that the fundamental change shown by these specimens is a severe chronic bronchitis and peribronchitis with destruction of bronchial musculature. This results in the dilatation of the bronchi so well demonstrated by the x-ray films. Probably the atelectasis consequent upon removal has caused a collapse of the saccules so that we can no longer see them except in the case of longest duration. Quite probably in this case many have reached sufficient size and attained a sufficiently thick fibrous tissue wall to keep them from complete collapse.

Harvey Nelson, *Secretary.*

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

FEVER THERAPY. Abstracts and Discussions of Papers Presented at the First International Conference on Fever Therapy. Edited by members of the American Committee. 486 pages. Price, cloth, $5.00. New York: Paul B. Hoeber, Inc., 1937.

THE PHYSICIAN'S BUSINESS. Practical and Economic Aspects of Medicine. George D. Wolf, M.D. Attending Otolaryngologist, Sydenham Hospital, New York City; Attending Laryngologist, Riverside Hospital, New York City, etc. 384 pages. Illus. Price, cloth, $5.00. Philadelphia: J. B. Lippincott Co., 1938.

MACLEOD'S PHYSIOLOGY IN MODERN MEDICINE. Eighth Edition. Edited by Philip Bard, Professor of Physiology, Johns Hopkins University School of Medicine, and Collaborators. 1,051 pages. Illus. Cloth binding. St. Louis: C. V. Mosby Co., 1938.

SIR KENELM DIGBY. Writer, Bibliophile and Protagonist of William Harvey. John F. Fulton, M.D. 75 pages. Illus. Linen binding. New York: Peter and Katharine Oliver, 1937.

ANNUAL REPORT OF THE SURGEON GENERAL, PUBLIC HEALTH SERVICE OF THE UNITED STATES. 164 pages. Illus. Price, paper, 60c. Washington, D. C.: Government Printing Office, 1937.

PROCEEDINGS OF THE THIRTY-FIRST ANNUAL CONVENTION. Association of Life Insurance Presidents. 254 pages. Illus. Paper binding. New York: Association of Life Insurance Presidents, 1938.

CONCEPTS AND PROBLEMS OF PSYCHOTHERAPY. Leland E. Hinsie, M.D., professor of Clinical Psychiatry, College of Physicians and Surgeons, Columbia University; Assistant Director, New York State Psychiatric Institute and Hospital. 199 pages. Price, $2.75. New York, N. Y.: Columbia University Press, 1937.

This book aims to be a preface to psychotherapy. The author asserts that it covers the general principles involved in the several schools of psychotherapy. He believes it undesirable to promote the interests of one school of psychotherapy. The Freudian psychoanalysis as it is applied today has, it is stated, but a limited field; it is usable in a mere fraction of psychoneurotic individuals, and it is of little public service therapeutically. He discusses in his text also the psychotherapies of Adler, Jung and A. Meyer.

With reference to therapeutic results, the lack of control data until very recently is noted. The fifth of the six chapters in the text is devoted to a discussion of "A Statistical Evaluation of Psychotherapeutic Methods" by Carney Landis, Ph.D. In his conclusion the author indicates that he inclines to the belief that "even if we cannot apply the laws of biometrics to our current conceptions of therapy, we can at least meet some of the preliminary requirements upon which the laws are based."

J. C. MICHAEL, M.D.

MATERIA MEDICA TOXICOLOGY AND PHARMACOGNOSY. Wm. Mansfield., A.M., Ph.D. 708 pages. Illus. Price $6.75. St. Louis; C. V. Mosby, 1937.

This book is written by a pharmacist as a text and reference book on the therapeutics, pharmacognosy, toxicology and posology of the official drugs of the United States Pharmacopœia XI and the National Formulary VI. It has one very interesting and valuable feature: the vegetable drugs are described singly with only one drug on a page and a picture of the crude drug is printed opposite the description. Following this there is a detailed description of the drugs of animal origin. There is a chapter on poisons which is interesting and valuable. This includes ways in which poisons may be taken, types of poisoning, symptoms, antidotes and treatment in general and in particular. The poisons which are used as drugs are described. This section includes most of the ordinary chemicals, such as arsenic, iron, local anesthetics, alcohol, ergot, etc. Finally, there is a large posological table with drugs arranged alphabetically and according to dose of liquids and solids.

There is a tremendous amount of facts in this book, but most physicians will find their more usual sources, pharmacopœia and the larger texts of pharmacology or treatment more serviceable. Pharmacists and perhaps doctors who do their own dispensing will probably find this worthwhile. It will be useful to doctors giving lectures to nurses.

For most physicians, this volume will be of very little value and the reviewer would not recommend its purchase for the personal library.

ACUTE LYMPHOCYTIC MENINGITIS*

E. M. HAMMES, M.D.

Professor, Neurology and Psychiatry, Medical School, University of Minnesota
Saint Paul, Minnesota

WALLGREN, in 1925 and 1926, described a new syndrome of central nervous system infection under the title of acute aseptic meningitis. He reviewed the reports of two epidemics which had occurred in France in 1910 and 1913 and which were supposed to have been an abortive type of poliomyelitis, and similar epidemics in Europe in 1922 and 1923 which had been diagnosed mild cases of encephalitis. The characteristic symptoms of these cases were severe headaches with neck rigidity and other evidences of meningeal irritation with ultimate recovery. Wallgren reported several similar cases and emphasized the importance of the typical spinal fluid findings.

Since then other cases have been reported in increasing numbers both in Europe and in this country. Many names have been suggested but the terms, acute lymphocytic meningitis or acute aseptic meningitis, have been most universally adopted. Viets and Watts published the first three cases in this country in 1929. Thorson reported the first case in this state in 1936 and stated that two cases had occurred at the University Hospital and five at the Minneapolis General Hospital.

Although the disease is still considered by some as an abortive form of the meningitic type of epidemic encephalitis, the course of the disease and the characteristic spinal fluid findings make it a distinct clinical entity.

The onset is usually quite sudden, rarely with convulsions. Headache is frequently the first symptom, increasing in intensity, so that the patient becomes bedridden within a few days. This is associated with nausea and vomiting, and occasionally photophobia. About this time neck rigidity manifests itself and the clinical picture is quite suggestive of a tuberculous meningitis with which it is frequently confused.

Repeated spinal fluid studies, however, enable one to arrive at the correct diagnosis. The spinal fluid is usually clear and under normal or slightly increased pressure. The cell count varies from a moderate increase to over 1000, depending on the severity of the disease. Most of the cells are small lymphocytes, in many cases 100 per cent. In the early stage of the disease, although the lymphocytes predominate, one may encounter polymorphonuclear leukocytes. These may be as high as 35 per cent although usually in smaller numbers, and are an index of the severity of the infection. The protein frequently shows a slight increase. The characteristic diagnostic findings, however, are that the spinal fluid sugar remains within normal limits during the entire course of the disease (50 to 75 mgm. per 100 c.c.), as do also the chlorides (720 to 750 mgm. per 100 c.c.). The colloidal gold curve is usually in the meningitic zone. In one of our cases (Case three), however, it gradually shifted from the meningitic to the syphilitic zone and finally gave a definite paretic curve. Viets and Watts and Warren reported similar findings in two of their cases. Although the spinal fluid does not contain clots, several cases have been reported where a delicate fibrin web developed several hours after its removal similar to what occurs so characteristically in tuberculous meningitis. No organisms have been found on smear, culture or guinea pig inoculation. A moderate leukocytosis is frequently found in the blood during the early stage of the disease.

*Read at the annual meeting of the Southern Minnesota Medical Association at Winona, Minnesota, August 11, 1937.

The course is usually a benign one. The temperature gradually subsides, the irritative meningeal signs disappear and the spinal fluid findings gradually return to normal. Repeated spinal drainage favorably influences the course of the disease and should be performed in every case. In the severe cases, delirium and even prolonged psychotic symptoms may manifest themselves, with an ultimate favorable outcome. Cranial nerve palsies or other organic signs are infrequent or only transient when present; choked discs may occur early in the course of the disease.

In contrast to encephalitis, these patients rarely develop any late manifestations or sequelæ. This is considered an important differential diagnostic point. Complete recovery is the rule. Only one death has been reported in the literature. A patient observed by Viets and Warren died on the fourteenth day of his illness, immediately after his second convulsion. Post-mortem studies revealed extensive perivascular infiltration and slight ganglion cell changes throughout the central nervous system, indicative of a marked encephalitis as well as meningitis. Although the nervous tissue reaction was a severe one, the authors felt that the pathologic appearance did not preclude recovery.

Acute lymphocytic meningitis usually develops in isolated cases. However, epidemics have been reported suggesting an infectious origin. Anderson and Wolff think that this disease has become more prevalent since 1920 than epidemic encephalitis. If this is true, it has not been recognized in the majority of instances. Eckstein reported an interesting epidemic of thirteen cases at Dusseldorf in 1930. Toomy reported a group of seventy cases occuring in an orphanage which housed three hundred and sixty male children and sixty-five adults. These cases developed within a period of twenty-one days. The clinical picture, spinal fluid findings and course of the disease were quite typical of acute lymphocytic meningitis. However, the blood picture examined in eighteen cases revealed a leukopenia with a high relative lymphocytosis. In a small percentage, a hemolytic streptococcus was obtained from throat cultures. In his paper Toomy states that twenty-five similar cases had been observed by Currier of Grand Rapids, Michigan, and fourteen cases by Ashton of Beckly, West Virginia. Dummer et al reported a small epidemic occuring in a group of twenty-two children during 1935.

Although no definite etiologic factors have been found in this type of meningitis, Scott and Rivers reported two cases in which a filtrable virus was obtained. The etiologic agent was isolated from the spinal fluids of these patients, and their serums possessed neutralizing antibodies for at least one hundred lethal doses of the virus from nine to eleven weeks after the clinical onset of the disease. However, in some typical cases this virus could not be demonstrated. Dominick reported three cases, two of which contained antibodies for the virus. He suggests that in those cases of lymphocytic meningitis where the organism is found or when the neutralization tests of the serum have positive results the term lymphocytic choriomeningitis should be employed. Rivers and Scott have further demonstrated that acute lymphocytic meningitis may be caused by etiologic agents other than this virus.

In the differential diagnosis, one must consider:

1. The various types of purulent meningitis which can be readily excluded from spinal fluid studies.

2. The abortive forms of poliomyelitis which may offer considerable difficulty except that in the early stages, polymorphoneuclear cells frequently predominate in the spinal fluid.

3. The cases of meningismus associated with acute otitis media and other acute systemic infections, in which the etiologic factor can readily be determined.

4. Tuberculous meningitis where a decrease in sugar and chlorides in the spinal fluid and the findings of the organism confirm the diagnosis.

5. The meningitic form of epidemic encephalitis which frequently offers the most difficult problem. The presence of localizing signs and lethargy, the sugar increase in the spinal fluid when present, and some manifestations of sequelæ are important diagnostic indications.

6. Syphilitic meningitis, which can be readily diagnosed from the positive spinal fluid findings.

We have observed seven cases during the past year, three of which are reported to illustrate the variations in the severity of the disease. One of our cases referred by Dr. L. N. Bergh of Montevideo, Minnesota, had a typical severe course of acute lymphocytic meningitis of four

weeks duration. During this period he had two convulsions. With the improvement in his meningitis, he developed a psychosis associated with delusions and hallucinations. He gradually improved and made a satisfactory recovery after four months.

Case 1.—A woman, aged thirty-nine, was admitted to the neurological service at Ancker Hospital on March 15, 1937. The family and personal history were negative except that the patient has always been mentally deficient. She completed the fifth grade at the age of sixteen. Because of her mentality it was difficult to obtain an accurate history. Apparently she developed a headache on March 12, 1937, which gradually grew worse. The next day she began to vomit. These two symptoms became more pronounced. She complained of vertigo and backache and was admitted to the hospital three days after the onset of her illness. The physical examination was negative. X-ray of sinuses and mastoids and lungs revealed no pathology.

The neurological examination was negative except for a rigid neck, and a moderate increase of all deep reflexes. The Kernig was negative. The blood count was normal, leukocytes 9,750. The urine was normal. The blood Wassermann and Kahn tests were negative. Twenty-five c.c. of clear spinal fluid under normal pressure were removed. The fluid contained a trace of globulin, 269 cells (94 per cent lymphocytes, 6 per cent polymorphonuclear); chlorides 704 mg. per 100 c.c.; sugar 78 mg. The spinal fluid Wassermann was negative; the colloidal gold curve negative; no organisms were found. The temperature and pulse were normal.

A provisional diagnosis of tuberculous meningitis was made. During her stay at the hospital the temperature was normal except on the second day when it was 100.6 for twenty-four hours. Her symptoms gradually subsided and she was discharged as recovered on her twenty-first hospital day.

Five spinal punctures were done.

Date	Cells	Chlorides	Sugar
March 16, 1937	269 94 per cent lymphocytes	704 mg.	78 mg.
March 17, 1937	790 90 per cent lymphocytes	712 mg.	72 mg.
March 19, 1937	647 all lymphocytes	708 mg.	74 mg.
March 25, 1937	172 all lymphocytes	706 mg.	78 mg.
March 27, 1937	28 all lymphocytes	710 mg.	70 mg.

Two months later she reported to the out-patient department because of a discharging right ear. This cleared up in ten days. There were no other symptoms or complaints.

Case 2.—A laborer, aged twenty-one, was admitted to the neurological service at Ancker Hospital on September 21, 1936. His family and personal history were negative. His present illness began about 10 A. M. on September 20, 1936, while helping a neighbor dig a basement. He developed a severe headache, throbbing in character which rapidly grew worse so that he had to discontinue work after two hours. He went to bed and two hours later began to have attacks of vomiting of a projectile type. About this time he noticed some neck rigidity. All these symptoms became more pronounced and he was brought to the hospital at 2 A. M. on September 21, 1936. At the time of admission his temperature was 102, pulse 100, respiration 24. The physical examination was negative except for a slightly injected throat. The neurological examination revealed marked neck rigidity and a positive Kernig sign. All cranial nerves were normal. All deep reflexes were moderately decreased, the left Babinski questionably positive. He complained of pain and tenderness in the muscles of both lower extremities.

The urine was normal; blood count normal except for a leukocytosis of 26,000; blood pressure, systolic 120, diastolic 70. A lumbar puncture made at 4 A. M. on September 21, 1936, revealed a slightly cloudy fluid and under slightly increased pressure. Sixty c.c. were withdrawn.

The spinal fluid contained 314 cells, all lymphocytes; chlorides 715 mgs. per 100 c.c.; globulin one plus; spinal sugar 83 mg.; Wassermann and Kahn negative; colloidal gold curve 0000012200, no organisms; protein 46 mg. A tentative diagnosis of acute poliomyelitis was made and 20 c.c. of convalescent polio serum was administered intramuscularly.

Course: Following the spinal drainage his headache and vomiting improved. On September 22, 1936, a cisternal puncture was performed and the spinal fluid contained 251 cells, mostly lymphocytes. His general condition improved, the temperature gradually became lower, was normal on the fifth day and remained so. The rigid neck and Kernig gradually disappeared, his symptoms subsided and he was discharged on October 24, 1936, thirty-four days after his admission to the hospital, apparently recovered. He was seen in the out-patient department three weeks later at which time he had no complaints nor abnormal findings. His leukocytosis dropped to normal after the third day. Eight spinal punctures were done, the last one on October 13, 1936.

Date	Cells	Chlorides	Sugar
September 21, 1936	314 all lymphocytes	715 mg.	73 mg.
September 22, 1936	251, 90% lymphocytes	720 mg.	74 mg.
September 25, 1936	340, 90% lymphocytes	740 mg.	75 mg.
September 28, 1936	462 all lymphocytes	690 mg.	..
October 3, 1936	460 all lymphocytes	710 mg.	72 mg.
October 5, 1936	192, 90% lymphocytes	750 mg.	70 mg.
October 7, 1936	188, 90% lymphocytes	720 mg.	..
October 13, 1936	36, 70% lymphocytes	720 mg.	..

Case 3.—A negro, a Pullman porter, aged thirty-five, was admitted to the neurological service at the Ancker Hospital on July 6, 1936. His family history was negative. His personal history was negative except that he contracted gonorrhea in 1928 and a chancre in 1929 for which he had received four "arm shots" and two "hip shots." His present illness began six days prior to admission to the hospital. On July first he had several severe chills, fever and "ached all over." Soon after he developed severe headache, pain and stiffness in the neck and back and generalized weakness. He had some nausea and had been very constipated since the onset of his illness.

The physical examination was negative. The neuro-

logical examination was negative except for a rigid neck, a positive Kernig and generalized tenderness. All cranial nerves, including the pupils, and all reflexes were normal. His temperature was 102.6; pulse 128; urine and blood count were normal except a leukocytosis of 12,450; blood Wassermann negative.

The spinal fluid was somewhat cloudy under increased pressure and 30 c.c. were removed. It contained a 2 plus globulin, 1,230 cells, 65 per cent lymphocytes and 35 per cent polymorphonuclears; chlorides 698 mg.; sugar 72 mg.; Wassermann and Kahn negative; colloidal gold curve 0000123310. Smear and cultures were negative for organisms. Immediately following the spinal drainage 30 c.c. of antimeningococcic serum were given intraspinally and intravenously because of the diagnosis of meningitis suspect.

Course: During the first eight days the temperature fluctuated between normal and 102 and pulse around 110. He was semi-delerious, extremely restless, had an occasional involuntary urination and complained of severe pain and neck rigidity. Because of the restlessness and confusion he had to be kept in restraint. All these symptoms gradually subsided as the temperature continued to be normal after July 14. From July 15 to July 27, two weeks after the onset of his illness, he complained of numbness and weakness of the right upper extremity and had some loss of motor strength of the right shoulder girdle muscles. This slowly improved and by August 14 he was up and felt well, but was kept in the hospital because of the continued pleocytosis in the spinal fluid.

Daily spinal drainage was performed during the first ten days and at frequent intervals thereafter. A total of thirty-four lumbar punctures was made, the last one on November 6, 1936. The highest cell count was 2,170 on July 15 and the lowest thirty-four on November 6; the lymphocytes varied from 60 to 95 per cent, while the remaining cells were mostly polymorphonuclear leukocytes. During the first ten days the spinal fluid was slightly cloudy, then became yellowish for a short period and then clear. The colloidal gold curve was in the meningitic zone until September 15, then quite rapidly extended into the syphilitic zone, and on three occasions presented a paretic curve. The Wassermann and Kahn were negative at all times; the sugar and chlorides were normal throughout; no organisms were found on smear, culture or guinea pig inoculation. After the paretic colloidal gold curve developed, the patient was placed on antisyphilitic treatment without any appreciable effect on the serology of the spinal fluid. Clinically he had recovered and left the hospital December 9, 1936.

Although this patient gave a positive syphilitic history, the normal pupillary findings and the negative Wassermann and Kahn, both in the blood and spinal fluid, exclude syphilis as the etiologic agent. However, it may have been a contributing factor in prolonging the pleocytosis in the spinal fluid.

Conclusions

1. Acute lymphocytic meningitis is a definite clinical entity characterized by symptoms of meningeal irritation, typical spinal fluid findings and a favorable outcome with repeated spinal drainage.

2. The etiologic agent evidently is a filtrable virus isolated by Scott and Rivers.

3. Seven cases have been observed by the author. Three are reported in detail.

THE PRESENT STATUS OF THE INSULIN-HYPOGLYCEMIA TREATMENT IN SCHIZOPHRENIA*

EDWARD F. ROSENBERG, M.D., FREDERICK P. MOERSCH, M.D.,
RUSSELL M. WILDER, M.D., and BENJAMIN F. SMITH, M.D.
Rochester, Minnesota

INSULIN-HYPOGLYCEMIA therapy for schizophrenia is in the forefront of medical thought today. As a result of the enthusiastic reports of Sakel and his followers, both here and abroad, and because of the favorable publicity given the treatment in the lay press, public interest has been aroused to a high pitch. Medical men and hospitals are being flooded by requests from anxious relatives to employ the treatment on their beloved ones who have fallen prey to this tragic malady.

In spite of the extraordinary claims for the insulin-shock treatment it appears premature to draw final conclusions regarding the ultimate value of this form of therapy. We have been impressed by the wisdom of the attitude of the Committee on Public Education of the American Psychiatric Association which in February, 1937 issued the following statement: "It is hoped and may prove to be a fact that the so-called insulin-shock treatment for dementia præcox will find a useful place among the forms of treatment for dementia præcox, but its exact value has yet to be determined and it can be definitely stated that it is not a specific, nor by any means a cure for all cases of dementia præcox. It would be a source of regret should the insulin-shock treatment be a means of holding out a false hope to the families of tens of thousands of sufferers from dementia præcox when this hope most certainly cannot be widely realized with the present-day knowledge of insulin therapy."

A survey of the medical literature reveals reports of some very glowing results in the treatment of schizophrenia by insulin-shock therapy. Thus Sakel[17] reported more than 70 per cent of complete remissions in cases of early schizophrenia. Müller's[13, 14] report of more than 300 cases reveals even better results. Berglas and Süsič[1] said that in a total of eighty-five cases 70 per cent of patients who had early schizophrenia obtained complete remission. At the meeting of the American Psychiatric Association in Pittsburgh in May of this year, figures of a very similar nature were reported. Summing up the various figures a fair statement would be about as follows: In cases in which the psychosis is of less than six months' duration, the recovery rate is said to be from 60 to 80 per cent; if the psychosis has been present between six and eighteen months, the recovery rate is 30 to 50 per cent, and in cases of chronic schizophrenia the recovery rate is 10 to 20 per cent.

Thus far but few voices have been raised in protest. Professor Berze,[2] Lichter and Lichter,[11] Langenfeldt[9] of Oslo, Adolf Meyer[12] and a few others have cautioned against accepting the claims of those who have reported so encouragingly on the results of the treatment.

We hold no brief for either side in this controversy. Certainly, any treatment, even if it holds out but slight hope, is worthy of a thorough trial. It may at least open the way to some new avenue of attack and keep up that needed stimulus so necessary in the pursuit of a problem that has seemed so hopeless.

We recently have brought to a conclusion the treatment of thirteen patients who had schizophrenia. We must acknowledge that our material is limited and does not represent patients who were very favorable for treatment. However, we feel that a review of our experiences may be of value to those interested in this problem.

The Method of Treatment

Descriptions of the insulin-shock treatment have been published in Europe by Sakel,[17] Dussik and Sakel,[4] Müller,[13, 14] Braunmühl,[3] Hoff,[6] Larkin,[10] Wilson,[21] and Schaeffer.[19] In this country adequate accounts of Sakel's methods have been given by Glueck,[5] Sakel,[18] Reese,[15]

*Read before the Society of Neurology and Psychiatry, Rochester, Minnesota, May 29, 1937; also before the Southern Minnesota Medical Association, Winona, Minnesota, August 11, 1937.
Since this paper was presented for publication, thirty-three patients have completed their treatment. Of this group, five made complete recoveries, three were moderately improved and twenty-five showed no improvement. Two of the five patients that recovered have had a recurrence of mental symptoms. One death was attributed to the treatment.

and Wortis.[22] We recently made a preliminary report of our work.[16]

In our work we have duplicated the original methods of Sakel as nearly as possible, but it

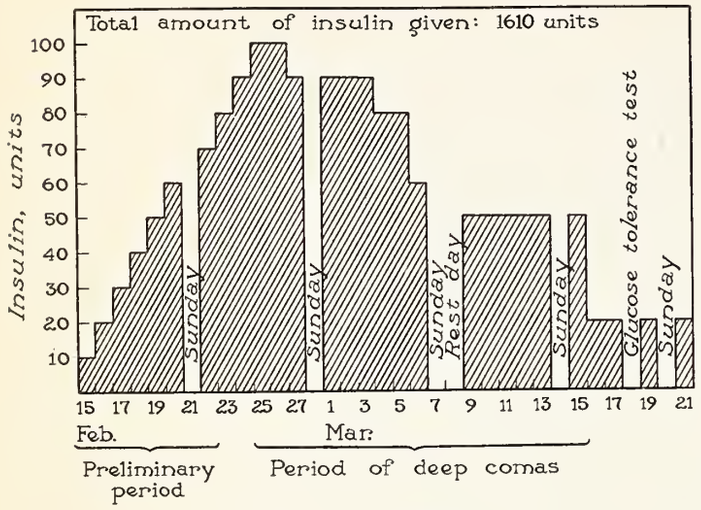

Fig. 1. Dosage of insulin in Case 8.

must be obvious at once that those who apply such a complicated procedure will have to evolve the method of handling numerous details through experience. A prime consideration in the treatment was the selection of patients. For our original group of patients we required that the physical condition of the patient be good. We insisted also that the responsible relatives be aware of the dangers of the treatment and be willing that it be undertaken. The Rochester State Hospital population includes relatively few patients who have schizophrenia of recent onset; consequently our cases have been those in which the psychosis usually extended beyond the critical period of six months.

Our working scheme has permitted us to handle approximately six to ten patients at one time. Breakfast is withheld and at 7 a.m., following the recording of the patient's temperature, pulse rate, respiratory rate and blood pressure, the insulin is injected. The pulse rate, respiratory rate and blood pressure are then recorded at intervals of thirty minutes until the morning's treatment is terminated.

The Dose of Insulin.—Our plan for the dosage of insulin is illustrated (Fig. 1) in Case 8, in which the patient improved during treatment. The treatment begins with the injection of ten units of insulin. This amount is increased daily by ten units until the coma dose is reached. This coma dose is repeated several days and then, if sensitivity to insulin develops, the dose is gradually lowered as a smaller dose becomes sufficient to produce satisfactory coma. When a sufficient number of comas have been induced, the dose of insulin is lowered to twenty units. This last period of small dosage is our equivalent of "Phase IV" of the treatment as outlined by Sakel.

The Termination of the Morning Treatment.—The effect of insulin, if not interrupted, would cause coma to persist an indefinite number of hours. It would, undoubtedly, be dangerous to prolong the coma unduly, and the following active measures are taken to terminate the hypoglycemia. At 11 a.m., four hours after the injection of the insulin, patients who have not become comatose are given by mouth 150 gm. of sucrose in chocolate flavored milk. Patients who have become comatose are allowed to remain in coma as long as one and a half hours (if the general condition permits). A nasal tube then is inserted and 150 gm. of sugar in water is allowed to flow into the stomach by gravity. These measures usually cause the patient to awaken within a few minutes.

Sakel expressed the opinion that short severe shocks are to be preferred to long light episodes of coma. Some workers (James, Freudenberg and Cannon[7]) have gone so far as to administer cardiazol in an effort to produce convulsions in addition to coma, in the belief that the convulsive reactions are of aid in bringing about more speedy improvement.

The Phenomena of Insulin Shock

Much has been written of the phenomena which one observes in cases in which schizophrenia is treated by this method. In our cases the first effect of a coma dose of insulin has been to cause drowsiness. This drowsiness in most instances has persisted for about two hours. During the period of drowsiness, pallor and marked perspiration are frequently but by no means constantly present. Following the stage of drowsiness, some patients exhibit a more or less wild motor and psychic excitement, lasting a variable length of time, after which coma appears. Others pass quietly from drowsiness into coma without excitement. It is during the phase of excitement, when it occurs, and during

the early stages of coma that remarkable neurologic phenomena of hypoglycemia occur.

During coma the respirations, the position of the patient in bed and his general condition require constant attention. This, together with frequent observations of the condition of the pulse, respiration, blood pressure and temperature, constitutes the special duties required in the nursing care of these patients (Fig. 2).

The patient in hypoglycemic coma presents a treatment problem which is similar in many respects to the problem of handling a patient during the coma of surgical anesthesia. Both require particular efforts on the part of the attendant to preserve the body heat, to keep the patient warm and dry, and to meet emergencies demanding immediate attention to prevent serious complications.

Subjective Reactions

A visitor observing the insulin treatments may infer from the patient's reactions that he suffers greatly. Powerful muscular contractions, grimacing, grinding of teeth, and extraordinary noises combine to present a picture of unmitigated misery such as accompanies few if any other medical procedures. It is very fortunate that, if this treatment does cause discomfort, the memory of the uncomfortable sensations does not persist. Patients cause no difficulty by refusing or being unwilling to take the treatment, because, they have no recollection of the past treatments and no patient has complained of discomfort. On being questioned, an occasional patient recalls a sensation of intoxication or dizziness as the last thing he remembers before slipping off into coma. One patient has written an excellent description of his sensations during the induction and recovery phases (Case 11). This description is an account of well-known sensations frequently experienced during induction and recovery from general anesthesia.

It is usual for the patient to have a splendid appetite immediately on reacting from the coma and he will usually devour sufficient food at the time of his noon meal so that he will more than make up for the calories missed because of omission of breakfast.

Dangers

Fifteen years of experience in the treatment of diabetes with insulin has proved that the symptoms of overdosage of insulin are not very dangerous. On the other hand, the degree of overdosage is much greater in the treatment of schizophrenia with insulin and occasionally serious complications may be encountered.

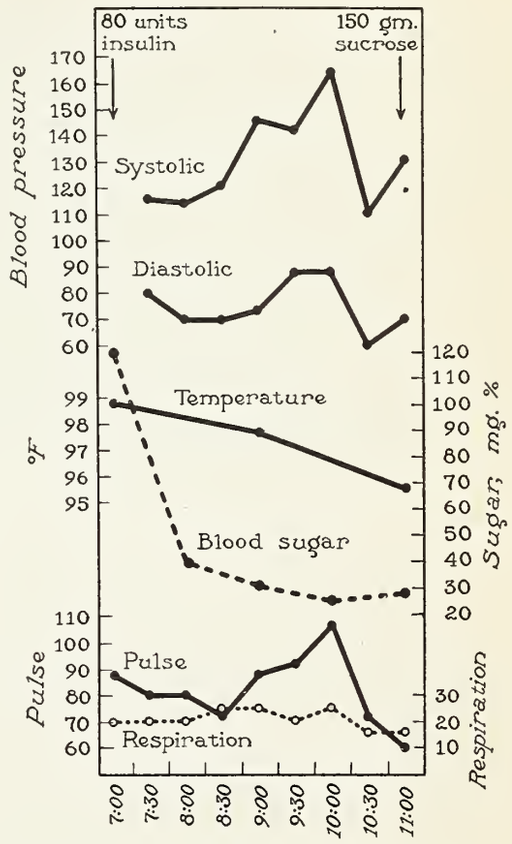

Fig. 2. Usual changes in blood pressure, temperature, blood sugar, pulse and respiration during insulin coma.

The coma initiated by hypoglycemia may persist even after the blood sugar has been restored to a normal level. We have observed two reactions of this type. Two patients failed to awaken promptly from coma after the administration of the usual sucrose by the nasal tube. Both were given dextrose intravenously and more sucrose by nasal tube, which increased the concentration of blood sugar. Coma continued for forty-eight hours in the first instance and then cleared. The second patient remained stuporous four days and Babinski's sign could be elicited on his right foot for thirteen days. In neither case has any evidence of these episodes remained. v. Pap[20] has observed similar incidents.

"After-shock" has occurred in five instances in our series of cases. These reactions are likely to occur in a case in which the patient eats poorly at the time of the noon meal. Rather severe hypoglycemic symptoms, even coma, may

TABLE I. TREATMENT OF SCHIZOPHRENIA (DEMENTIA PRÆCOX) BY INSULIN-HYPOGLYCEMIA

Cases*	Age, Years	Type of Schizophrenia	Duration of Psychosis, Years	Length of stay in Hospital, Months	Prognosis by Usual Treatment	Treatment		Results

†Third admission.
‡Some transient improvement.
§Second admission.

appear late in the afternoon. "After-shock" is inconvenient but not dangerous; in cases in which it has occurred the patients have responded promptly to the intravenous administration of glucose. Feeding carbohydrates during the afternoon usually prevents "after-shock." Our routine now includes the administration of 50 to 75 gm. of sucrose in the form of chocolate candy at 3 p.m. and at bedtime to all patients who have received insulin during the morning.

In man, epileptiform attacks occur occasionally during hypoglycemic shock; in dogs, such attacks appear very frequently. These attacks yield promptly to the administration of sugar and epinephrine, and it has been our practice to terminate the hypoglycemic state whenever the attacks become severe. Some writers, as Küppers,[8] do not interrupt the treatment when convulsive attacks appear. This appears to us to be somewhat hazardous and perhaps unnecessary. Symptoms of circulatory failure have not occurred in our cases and records of the pulse and blood pressure do not show any instances of alarming change during treatment. Young,[23] of Omaha, recently reported one death due to pulmonary edema and one death due to cardiac collapse.

Results

Throughout our work we have adhered to a policy of attempting to make observations as objective as possible. We have made a complete physical, psychiatric and laboratory survey of each patient before treatment was undertaken. We have recorded by photographs and by means of moving pictures the appearance and behavior of each patient before the treatment was begun, as we feel that these data afford valuable evidence in the estimation of any changes which may appear to have occurred as a result of the treatment.

In the thirteen cases which are the basis of this report (Table I), the type of schizophrenia was as follows: hebephrenic in seven cases, catatonic in five cases and paranoid in one case.

Hebephrenic Type.—No improvement was noted in six of the cases in which the schizophrenia was of the hebephrenic type but slight

improvement occurred in one case (Case 6). The outstanding features in this case may be found in the following history.

Case 6.—The patient was a man aged twenty-six years. The psychosis had been present for fifteen months before the insulin-shock therapy was started. He was very untidy; he had a fixed expression, and there was no spontaneous speech. His voice was monotonous, his mood was absolutely indifferent, and he collected all sorts of odds and ends in his pockets, including a match box which he usually kept filled with butter or some other food. He could not be induced to do work of any kind.

At the completion of the treatment he was a little more careful of his dress than he had been. He would read papers and magazines, he would help willingly in the ward work and in the occupational therapy pavilion. His movements remained slow and deliberate and his facial expression remained fixed and staring. The general opinion is that the amount of improvement attained in this case would hardly justify the prolonged, difficult and somewhat dangerous treatment, namely forty-eight deep comas in sixty-four treatment days.

In two other cases (Cases 3 and 4) in which the schizophrenia was of the hebephrenic type the patients experienced transitory changes in their psychoses and for a short time it appeared as though they might improve. At the completion of the treatment, which included forty-seven and thirty-eight deep comas respectively, the patients were unimproved.

Catatonic Type.—The two cases (Cases 8 and 11) in which the schizophrenia was of the catatonic type, the patients improved markedly during the course of the treatment. A summary of the events of these two patients follows:

Case 8.—The patient was a man aged thirty years (Fig. 3). His birth and development had been normal. When he was first admitted to the hospital in August, 1930, psychotic symptoms had been present for one month. He remained in the hospital until June 20, 1931; at that time he was markedly improved and was allowed to return to his home. He was readmitted to the hospital in August of 1934; at this time he was negativistic, sullen and uncommunicative. He improved slowly and was paroled in April of 1935. He returned home and later worked on a farm. He was admitted to the hospital, for the third time, August 27, 1936. For two months he had not shown any interest in his work. A few days before this he had struck his sister and had tried to tear the clothes from his brother. He had stood in one position for long periods. Mental examination at the time of admission was impossible because he failed to answer questions. There was no spontaneous speech but he exhibited marked flexibilitas cerea.

Between August, 1936, and February, 1937, there was no detectable change in his mental condition. At the time the insulin treatment was started it was his habit to sit quietly and apathetically about the ward. At

Fig. 3. Patient in Case 8 (catatonic dementia praecox); *a*, before treatment; *b*, after treatment.

times he refused to eat. There was no spontaneous speech and his mental status could not be assessed because he remained mute. The result of general and neurologic examination was negative except that catalepsy was marked.

The insulin treatment was started February 15, 1937 (Fig. 1). On February 18, profuse sweating appeared following the administration of 40 units of insulin. On February 22, 80 units of insulin was administered at 7 a.m. At 11 a.m. a condition of wild motor and psychic excitement was present. The patient made noises, screamed, threw himself around in bed and made powerful forceful thrusts and jumps. After he recovered from the hypoglycemia he spoke freely but was very silly. A half hour later he would no longer respond. Between February 23 and March 6, deep coma was induced daily (except for a rest day on Sundays). On March 6, following the administration of the usual dose of sucrose (150 gm. in 500 c.c. of water) at 11 a.m. he failed to respond and at 1:45 p. m. 25 gm. of a 50 per cent solution of dextrose was administered intravenously. At that time he was in deep coma; salivation and stertorous respirations were present. Ankle clonus and Babinski's signs were present bilaterally. At 2:00 p.m. he had not responded to the intravenous administration of dextrose and 1,000 c.c. of a 20 per cent solution of dextrose was injected slowly into a vein. In addition, 150 gm. of sucrose in water was administered through a nasal tube. At 6:30 p.m. he had not responded to the treatment. His skin was dry and there was urinary incontinence. The value for the blood sugar was 190 mg. per 100 c.c. The pulse rate was 82 beats per minute and there were 24 respirations per minute. The pupils were 2 mm. in diameter and reacted to light. On March 7, his condition continued the same all day. March 8, the stupor had cleared, and the general and

gross neurologic examination did not reveal any abnormality.

Deep comas were induced on March 9, 10, 11, 12, 13 and 15. Beginning on March 9, a remarkable change appeared in his condition. His movement seemed gradually to become more free. Flexibilitas cerea dis-

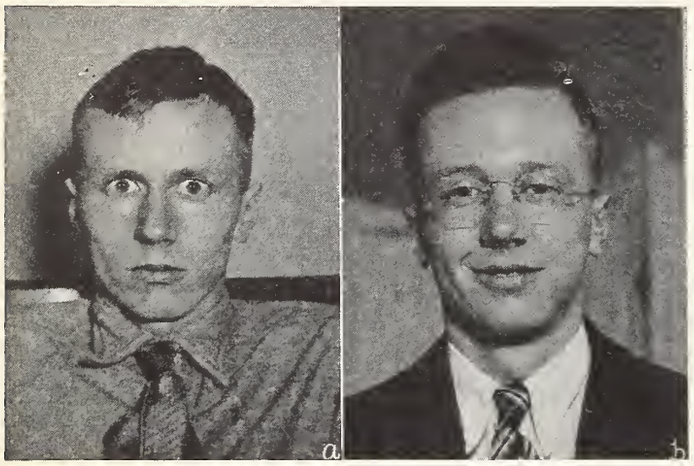

Fig. 4. Patient in Case 11 (catatonic dementia praecox); *a*, before treatment; *b*, after treatment.

appeared. The grimacing ceased. He began to speak freely with doctors and attendants. His gait became free and purposeful. He was sent to the occupational therapy pavilion in the afternoons, where he began wood-carving. His speech was silly at times and it occasionally was irrelevant. He did not seem to have much insight into his condition. He did state, however, that he realized he had been "mentally sick." He could describe his former jobs in an upholsterer's shop and in a bowling alley. He spoke freely of his previous earnings and discussed his home conditions intelligently. On March 16, the dose of insulin was decreased to 20 units and this small dosage was continued daily until March 21, after which insulin treatment was discontinued.

On April 26, 1937, he was paroled to the care of his family. He was neat, spontaneous speech was normal and he addressed the physician in an intelligent manner. He smiled and was good humored. He did not have a very good mental grasp of the events of his illness (he thought it might have resulted from smoking, although he had only smoked occasionally, or from drinking, although he had confined his drinking to an occasional glass of wine). He was well oriented as to time, place, and person and his memory for the events of his own life was excellent. His grasp of current events was very poor; he knew nothing of the current Spanish Civil War or of the abdication of the English king. He could calculate accurately and his speech throughout the examination was relevant and logical. He denied hallucinations and no delusions were expressed.

Case 11.—The patient was a man, aged twenty-two years (Fig. 4), who was a senior in a university. The past history was irrelevant. His mother said that he always had been somewhat moody and quiet, but he had been an average student. The patient was admitted to the Rochester State Hospital on January 27, 1937. During the preceding summer he had seemed unusually preoccupied and very quiet. He had started his senior year at the university in the fall of 1936 and while he had been at home he had spent most of his time studying. About December 1, 1936, his mother had noted that he seemed to be having difficulty in concentrating; he would scowl and keep pressing his forehead with his hand while reading. He had become more peculiar until January 1, 1937, when he had to be removed to a sanitarium because he refused to eat.

On examination prior to treatment he refused to speak and was filthy in his habits. He would protrude his tongue on command and allow the examiner to prick it with a pin, without evidencing any pain. There was marked flexibilitas cerea and he had to be fed almost entirely with a tube. He had lost 24 pounds (10.9 kg.). Routine laboratory procedures including serologic tests for syphilis did not reveal any abnormality.

Insulin treatment was started March 17, 1937. One hundred and twenty units of insulin produced satisfactory coma on April 1. He experienced a rather marked "after-shock" about 6 p. m. on April 8.

On April 9 the usual dose of 120 units of insulin produced a deep, satisfactory coma. This coma was terminated at 11 a.m. by feeding with a nasal tube. At 2 p.m. he was talkative but very peculiar. He answered to "how do you feel" by a long pause and then nodded his head slowly up and down and finally said "pretty good." He talked with the ward attendants about his meal and hummed a song in tune with a nearby radio. At 8 p.m. he refused to answer questions and would not look at the examiner.

The usual morning coma was induced on April 10. At 1 p.m., he was seen washing his face carefully and it was observed that his movements were free, whereas he previously had been very stupid and rigid. When he finished he smiled a greeting and stopped to chat. He was "feeling much better." He knew that he had been ill. He said that he had been unable to eat or talk because a voice told him not to do so.

On April 13, the dosage of insulin was reduced to 20 units daily; sugar was administered two hours later. Two hours after the insulin was injected the patient became comatose and presented a striking instance of insulin sensitization. He was sent to the occupational therapy pavilion on this day and began the caning of a chair. He was amenable, polite, quiet and good-natured. He smiled naturally when speaking and was anxious to please. He described the sensations of the insuline treatment as follows: "One feels before unconsciousness comes, not very sleepy but as though one wanted to move or arise from bed. It took much effort to move my arms, legs or body with much deliberation beforehand. When I moved any part of my body my mental condition changed." Concerning his awakening from the insulin coma he said: "Mentally, I

felt a space separation between myself and the world. Voices and other sounds came to me clearly but they were considered as coming across space, myself being on the opposite side from where voices and sounds came. My head felt as though it were expanding from within, causing mental pain. The sickening headache which resulted would continue for about two seconds, lessen in degree, then in two seconds become more intense, then lessen." When he was paroled on June 4, he was in excellent condition.

In the three remaining cases in which the schizophrenia was of the catatonic type the patients were not improved.

Paranoid Type.—Only one patient who had the paranoid type of schizophrenia was treated. This patient did not show any improvement.

Summary

Thirteen patients who had schizophrenia have been treated by the method of insulin hypoglycemia. Of these patients, ten were unimproved, one was slightly improved and two were markedly improved. The results of our work in the treatment of schizophrenia by the method of insulin hypoglycemia have not been as encouraging as those reported by Sakel. There may be several reasons for this difference. First, the patients were not treated at the most favorable time, and second, we have been cautious about permitting the continuation of convulsive manifestations which are now looked upon as desirable.

Regarding the two patients who improved markedly, the first had improved spontaneously on two previous occasions from similar attacks and there seems to be no way of assuring ourselves that he might not have recovered spontaneously in this instance. It does seem proper to assume that the treatment hastened the recovery. The second patient who improved was a young man who had catatonic schizophrenia; we feel that he would have been given a fair prognosis with the usual methods of treatment. However, there is little doubt that the treatment brought about his speedy improvement. We believe that the insulin-hypoglycemia treatment is a heroic form of therapy and should not be used haphazardly. Our results, while not too encouraging, justify further work in order to evaluate the results of the treatment and possibly point the way to added therapeutic measures. Accordingly, we have recently placed under treatment a group of twelve female patients who were suffering from schizophrenia.

Undoubtedly, the selection of patients must play an important rôle in determining the usefulness of this type of therapeutic procedure. Rules to be followed in this selection are not apparent from our work. A review of the literature is also unavailing in an attempt to settle this point beyond the fact that the more recent the onset of the psychosis the more favorable is the prognosis.

Uncertainty exists as to how many comas constitute a complete course of treatment. In our work, when improvement has not appeared after the patient has experienced twenty-five to forty satisfactory comas, we have concluded that the treatment is unavailing. Some workers have employed as many as 200 comas without beneficial effect. From our experience we would say that if a patient shows no improvement after forty comas the treatment should be discontinued.

Results obtained by us up to this time suggest that much more work will be required to provide a firm foundation for the extraordinary claims which have been made for this method of treatment.

Insulin treatment of schizophrenia demands of those who attempt it continuous watchfulness and a readiness to act in emergencies, which is based on definite knowledge of the situations at hand. The procedure deals with helpless patients in coma. Violent epileptiform convulsions are an ever-threatening menace. Cardiovascular, respiratory and cerebral calamities have been reported. Other dangers may lurk in regions incompletely explored. Accordingly, this method of treatment should be employed only in hospitals with trained personnel and a physician must always be at hand. The personnel of the insulin treatment ward should be well organized and should be similar to the modern trained operation room force in efficiency and readiness to act. To do less is to expose patients to unjustifiable risks.

We wish to express our appreciation to the Eli Lilly Company for supplying us with insulin for this work.

MEDICINE: A CO-OPERATIVE BUSINESS, A NON-COMPETITIVE PROFESSION*

B. J. BRANTON, M.D., F.A.C.S.
Willmar, Minnesota

DR. ALAN DE F. SMITH in a current issue of *Surgery, Gynecology and Obstetrics* writes a short biographic sketch of Dr. Russell A. Hibbs, and I wish to quote from it as follows:

"To those who knew him best his greatness lay even more in his fine spiritual qualities, in his never failing conviction that the truth must always prevail, in his steadfast adherence to any course that he believed was right, and in that rare gift of leadership which inspired all those who served under him to give the best that was in them and to feel that to work with him was a privilege. He always maintained that any accomplishment that was made in the advancement of medicine must come from a deep sympathy of the doctor for his patient and from his real concern in making him well."

What a privilege it must have been for him to be able to express in such beautiful words his honest opinion regarding a colleague and his worth to society. What a satisfaction to have been associated with a man of such fine accomplishments. What an honor to live so that we may leave behind us such sentiments of love to be expressed by those that we have worked and toiled with. That is the result of work well done, purposes accomplished, a life well spent.

Are we each of us devoting ourselves to our fellow men for the good we can accomplish or purely for selfish reasons? Is the practice of medicine wholly mercenary or purely sentimental? Are we doing our part in the economy of the state and nation, or are we shrugging our shoulders and shifting the burden on the heads of others less able by education or learning to carry it, with the possible regimentation of medicine to the purposes of the State as the penalty for our lack of interest?

Two thousand years ago there was born in Palestine on the banks of the Jordan the greatest Teacher and Physician of all times. He taught the gospel of love and peace to all mankind. He said, "Love your enemies." Men have said His teachings cannot be carried out in this essentially practical and competitive world. Experience, the leveler of all men's thoughts, teaches us that it can and should be as truly practical now as then.

Ambition, the young man's spark plug, gives way gradually to a fuller realization of the need of tolerance in most men's lives in later years. What we need most in America at present is to submerge that mythical ideal of success, the accumulation of wealth, in a development of American standards of just dealing.

If fair dealing for mutual welfare has been found so essential between lawyers, bankers, and business men generally; if friendship is a great and indispensable attribute in business, then

*Presented before the Northern Minnesota Medical Association, Virginia, Minnesota, August 27, 1937.

aren't we, as practitioners of the most sacred calling on earth, remiss if we do not develop a sense of mutual understanding of each others' problems, both economic and professional?

Thoreau once wrote, "If you have built castles in the air, your work need not be lost; that is where they should be. Now put foundations under them."

We are in Minnesota, I believe, putting solid foundations under our professional buildings. Nowhere are higher ideals of practice promulgated than here. We have not builded on the shifting sands. The 2,300 members of our State Association are an essentially learned and highly developed type of men. They have to be. The people among whom they work demand the best in service. We have built their demands up to a high plane. We cannot and will not let down this faith.

The standard of work which we have carried on during the late disagreeable depression among the so-called indigents gives the lie to those who say "medicine" has not done its share to make the lot of the people more tolerable. The long hours of service, the worry of nights of vigil have all been the same even though the incomes of physicians have shown a lessened figure from month to month. We have carried on medicine's unswerving traditions with unfaltering devotion. It is my belief that this "carrying on" through troubled times will be rewarded many fold in the future if we do not lose faith in each other. We are our brother's keeper to no small degree. Elbert Hubbard, that inimitable philosopher, said, "Do not lose faith in humanity. There are over ninety million people in America who have never played you a single nasty trick."

Many of us can remember when Dr. So-and-So would not speak to Dr. So-and-So. When to speak of a man's competitor was to bring down wrath and words of vituperation of unmentionable degree. The Hippocratic Oath was a thing forgotten since the day of graduation. The doctor's family were victims of unjustifiable censure. Small towns were divided into two camps, each with their medical man, much after the custom among ancient tribes of aborigines.

Has this changed today? Have organizations such as we have meeting here changed this attitude to a marked enough degree or are we still in the transitional state?

It is my belief that we have changed, at least to some degree. The change is not marked enough, but surely is gaining ground toward the ideal, a sincerely united profession.

Statistics show that the number of physicians practicing in states such as ours is just about keeping up with the population; that, while good roads and automobiles have made it easier for men to cover larger territories, new modes of treatment of disease, the intricacies of living and even the good roads and automobiles themselves have added to the work of the man of medicine. Industry and its insurance have entered the picture. Public health measures draw their workers from the graduates in medicine, thus lessening the number available for private practice.

There is work for all who seek it. No one needs to loiter at the door of the temple of Æsculapius. He who searches shall find. The workers are many but the opportunities are threefold.

The youth who looks through colored glasses, colored by the present trend of economic thought, into the future and sees no opportunity for him will find that the boy with imagination has passed him and has reached the goal of his desires. He is the master, teacher, and leader of the generation.

The success of coöperative enterprises in this State has placed Minnesota at the head of the states of the Union in this type of business; but back of coöperatives are years of solid thought. History but repeats itself and passing time finds but few changes in the economy of the world's wants. The mountains do not move though the winds and hurricanes harass them with their fury. The vast amount of water in the body of the oceans does not change though the waves roll over them.

In 1879 Roswell Dwight Hitchcock wrote "The Socialist" and in it gave us the picture of communism as we know it today. So every profession and business has found, passing down through the ages, that there is strength in numbers, that concentrated thought does the most good for all, that coöperative organizations with strong leadership are successful and easily survive the ravages of time.

Medicine, to keep its place in the fore of professions and protect its members, must foster the spirit of coöperation, must become a solid unit of economic thought, must forget petty jealousies and bickerings between individuals.

Cicero once said, "Men condemn because they do not understand." To better understand a man is the spirit of better coöperation. Society asks this of the man of medicine. Are we giving it?

While we sit at this meeting we are making resolutions to practice better medicine in the future, to live and forget past differences, to think and speak well of our confreres, to more fully enjoy that abundant life which we hear so much about. Can we and will we carry these same resolutions into effect when we reach our several homes? Why not endeavor to close the gap of unfriendliness between the door of your neighbor's office and your own. If in union there is strength and from fellowship and association come admiration, we can well remember this: "Man's conscious influence, when he is on dress-parade, when he is posing to impress those around him, is wonderfully small. But his unconscious influence—the silent, subtle radiations of his personality, the effect of his words and acts, the trifles he never considers—is tremendous."

From this day forth let our competitor be our coöperator; coöperation, not competition, our motto. An old friend of mine wrote the following after years of sorrow. It made a lasting impression on me. I give it to you:

I've shut the door on yesterday, its sorrows and mistakes,
I've locked within its gloomy walls past failures and heartaches,
And now I throw the key away to seek another room,
And furnish it with hope and smiles and every springtime bloom.
No thought shall enter this abode that has a hint of pain,
And every malice and distrust shall never therein reign.
I've shut the door on yesterday and thrown the key away,
Tomorrow holds no doubt for me since I have found today.

Tomorrow will hold no doubt for us if we have found each other today and are determined to extol each man's good qualities above his faults.

Let us make of medicine a coöperative business, a non-competitive profession.

MEDICAL TOUR OF SOUTH AMERICA

O. A. OLSON, M.D.
Minneapolis, Minnesota

UNDER the auspices of the Interstate Post Graduate Association of North America, a party of physicians visited the Universities of South America in the spring of 1937. This association for the past fifteen years has conducted clinical tours to Europe. This is the first visit to South America. There were twenty-six members in our party. The voyage was delightful, the kind one associates with the South Seas. The Neptune party was a new experience to most of us. Continuous pleasant weather banished sea sickness and made weather reports unnecessary.

On the morning of April second we entered the harbor of Rio, the most beautiful in the western hemisphere. As we passed the Sugar Loaf we saw the city spread out along the beautiful beaches. The harbor, twenty-five miles long, offers a beautiful vista as far as the eye can see. Rio is a city in the latitude of the tropic of Capricorn and its climate is similar to that of Havana. It is the capital of Brazil, a country larger than the United States and abundantly supplied with natural resources. The Amazon Basin, which was once an inland sea, contains rivers, mountains, plains and immense forests.

Many of the hospitals throughout South America are supported by benefit associations whose memberships vary from twenty-five to seventy-five thousand. One Catholic institution in Rio has thirty thousand members. The fee which one pays varies with age. It is approximately one hundred dollars for men and one hundred ten for women. The fee is paid when one joins and entitles the individual to free care for life, hospitalization, physicians, drugs, lawyers, x-rays, burial expenses, grave and grave markings. The reason life care can be given for such a small amount is due to the fact that the institution is endowed. The doctors are not paid.

The old Emergency Hospital at Rio, an efficient institution, has a fleet of ambulances always on call. The doctors are government employees and receive fifty dollars a month for part time and one hundred dollars for full time.

The Beneficencia Portugeza hospital is a beautiful building said to have cost ten thousand dollars per bed. Here we saw Dr. Gudin demonstrate his method of total sterilization. Operating room, dressings, surgical instruments and sponges are sterilized by formalin method. This occurs in a hermetically sealed, air conditioned and air filtered operating room. The amphitheater is above the operating room and one looks down through glass. The operating room is set up and formalin is introduced into the room under a valve control. After a certain time this is neutralized by ammonia and the ammonia neutralized by sulphuric or tartaric acid. Dr. Gudin claims that with care three or four clean operations may be done with one sterilization. At the time of the operation all persons in the room are completely gowned, including the feet. Surgeons are then free to touch anything about the room. If a sponge is dropped on the floor it may be picked up and used within the abdomen without danger of infection. The doctor claimed that by this method wound infection is much less frequent than by the method ordinarily used (Fig. 1).

We visited the Hospital dos Espostos, a hospital for abandoned children. Dr. Jose Martinho da Rocha is the director. Children brought to this hospital are passed through a hole in the wall. Persons leaving the child ring a bell to announce the arrival of the child. Sometimes the name of the child is left, sometimes it is not. The hospital takes care of all children who are left there. At the time of our visit there were seven hundred and fifty children in the institution and two hundred and fifty of them were infants. The children are educated and taught trades in the hospital. There were many cases of lues, tuberculosis and dysentery among the children. Their mortality from syphilis is 30 per cent in babies under one year of age. The diseases most common in children in Brazil are lues, tuberculosis, malaria and worms.

We were invited to a reception at the Brazilian College of Surgeons. Professor Jayme Poggi delivered an address of welcome to the doctors from North America. Membership in the college is limited to forty and is by invitation only.

At the Deutsches Krankenhaus, Dr. Maurity Santos, who is a very skillful surgeon, did a

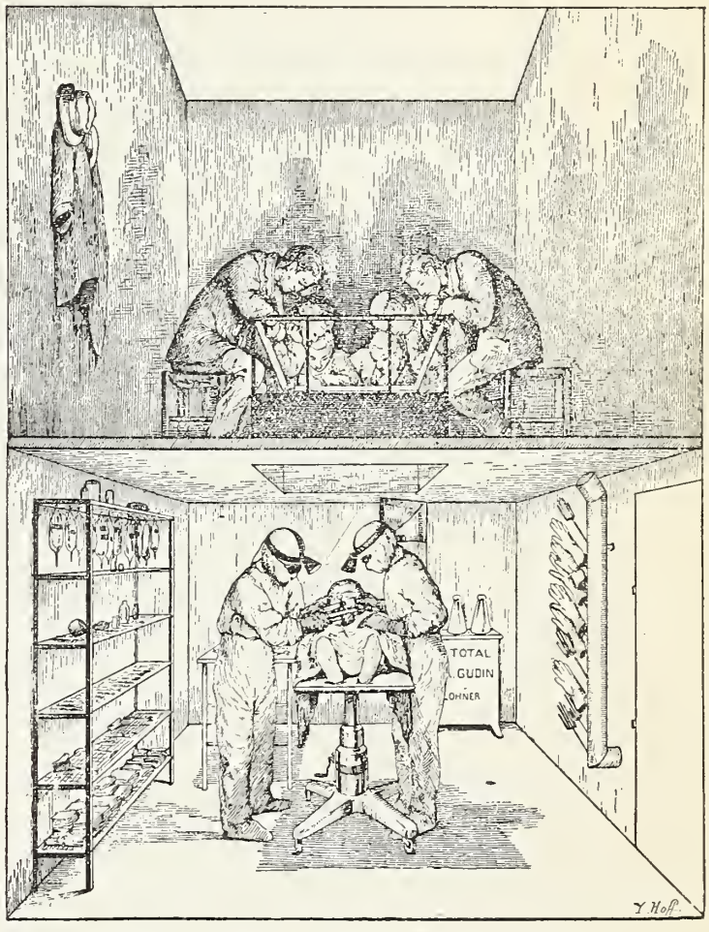

Fig. 1. Gudin's method of total sterilization.

vaginal hysterectomy for cancer of the cervix. No radium is used for cancer of the cervix in this institution. Dr. Santos also did a resection of the rectum for strictures from granuloma inguinale, a very common disease in Brazil. He used his own method, doing a combined abdominal and perineal operation, first liberating the diseased bowel through the abdominal opening, then, by an incision to the side of the rectum, resected the rectum and the diseased bowel, saving the sphincter. The proximal end of the bowel was then pulled through the anal opening and was split for several inches, each half being sutured to the buttock. A small tube was inserted into the bowel and four strips of iodoform gauze were placed into the ischiorectal fossa. The split portion of the protruding bowel was then allowed to slough. Dr. Santos has operated in fifty such cases. All cases showed a positive Frie's test.

Our medical section made the rounds with Professor Annos Dios in the clinic of Professor Clementino Fraga. He showed a variety of medical diseases, also demonstrated studies of bile chemistry pertaining to acidosis and alkalosis. In this hospital the government maintains a meteorologic station and for twenty years they have studied and correlated the effect of atmospheric changes on disease. Professor Dios concludes that certain atmospheric and meteorologic changes are responsible in part for certain complications such as pulmonary hemorrhages, typhoid hemorrhages, post-operative bleeding and shock as it appears following surgery. When the weather is too hot or the humidity is too great, they avoid operating except in emergency.

On April eighth we went by rail to Sao Paulo traveling through interesting mountainous country. Here and there the valleys were studded with ant hills, some as high as a man's head. Sao Paulo, named after the prophet, is situated on a plateau, has a delightful climate and its people are an energetic populace. The city has doubled in the last six years and now has a population of one million two hundred thousand. It is an industrial city, the "Chicago" of Brazil.

At the Santa Casa hospital Professor Ramos demonstrated cases of lipoid nephrosis showing a transition of this disease into parenchymatous nephritis, also aneurysm of the aorta, with erosion of vertebræ and ribs. He showed cases of Ayerza's disease, claiming that this is not a pathological entity and should not be designated nosographically as a disease. It might well be called black cardiac disease characterized by polycythemia. Dr. Ramos presented cardiac cases well worked up; extensive studies of electrocardiographs in cases of bundle branch block.

The Pro Matre Paulista Hospital is a modern, private maternity hospital of fifty beds, owned by twelve physicians, and has an open staff. They have portable incubators for premature children which are used to bring in cases for hospitalization.

At the Sanitoria Santa Catherina, a private hospital, Professor B. Montenegro did a gastric resection for ulcers of the stomach, using a technic which he developed. The operation was done under spinal anesthesia with one assistant, one interne and no clean nurse. His technic is used at the University and we saw students doing dog surgery, using his technic, for gastric resections. It is a simplified procedure and enables him to do a resection in one hour. He prefers gastric resection, removing approximately two-thirds of the stomach, in preference to all other operations for both gastric and duodenal ulcers. Dr. Montenegro, who formerly was professor of anatomy, received his surgical training under John B. Deaver in Philadelphia. He has done about twelve hundred gastric resections for ulcers. The mortality in the first 622 cases was 4.5 per cent. He has lowered his mortality in the last series. In his first 500 cases three cases of jejunal ulcers developed; none has developed in the last 700. He thinks this is due to the fact that he now does a more extensive resection. He uses the Van Slyke method of carbon dioxide determination in the blood as an indication for the use of glucose and subcutaneous saline. Glucose is often used preoperatively but never post-operatively unless there is special indication. Blood transfusions are seldom done.

He thinks that megacolon, megaureters and cardiospasms are all due to deficiency of vitamins B and B^1. Cardiospasm, called "Ecclasia," is very common on the coffee plantations of Brazil. It is not the same as Hirschsprung's disease, which is congenital. Ecclasia is due to paralysis or inability of the various sphincters in the large bowel to open. The spasm of the various sphincters of the colon, including Cannon's sphincter at the hepatic flexure and including spasm of the voluntary sphincter at the rectum, is due to vitamin B deficiency, which is responsible for the lesion in Auerbach's plexus. He believes that the spasm of the internal sphincters could be cured by dilatation if the sphincters could be reached, but there is no way of reaching them except surgically, by doing an open stripping operation, cutting the muscular layer down to the mucosa similar to the Ramstadt operation. He also believes these cases should be treated postoperatively with a general high vitamin diet. We were shown a case of common duct drainage in which the duct contracted under the influence of morphine. Lipiodol was injected into the common duct. When morphine was given, the lipiodol was forced back into

the pancreatic ducts showing that morphine caused contraction of the sphincter of Oddi.

On the afternoon of April eighth we visited the Butantan Institute where Professor Alfrania Amaral, a graduate of the Harvard School of Hygiene in 1924, is director. Fifty years ago this was a private institution for the study of smallpox and plague. It has now been taken over by the state, and it is practically self-supporting. The institution, consisting of many buildings and large grounds, is divided into twelve departments and research is conducted in a variety of scientific problems pertaining to Brazil. Smallpox vaccine is made which can be injected under the skin and does not cause a sore. This was first developed at the Rockefeller Institute. In the department for the study of fertilization, they are trying to develop better fodder, grain, etc. They grow oats from Australia, crossing it with Brazilian oats to improve its yield. A school is also conducted for the children of the employees. They provide a general education for the children and also educate them in special fields of work of the institution with the idea of thereby training future workers for the institute. Professor Amaral stated that it may well be that a child of the laboring man of the institute may become its director. The department of propaganada spreads knowledge of their findings among the people of Brazil. The department of records has been adopted from the United States. Bi-weekly meetings are held in which all departments exchange information. Practically all papers are published in Portuguese.

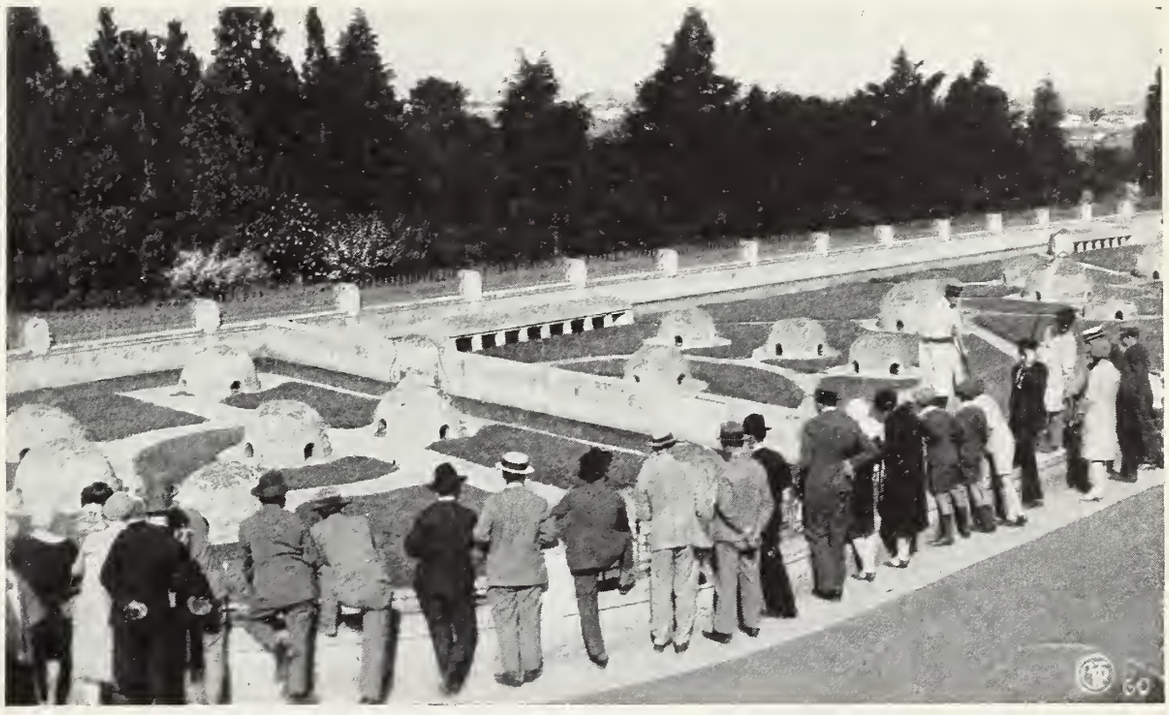

Fig. 2. The Butantan snake farm.

The Butantan snake farm (Fig. 2) comes under the department of biology. There are three types of poisonous snakes: rattlers, vipers and cobras. The rattlers and vipers are found in Brazil. Three types of antivenom are made: one for the rattler family, one for the viper and one that is polyvalent. When not certain of the reptile the polyvalent serum is used until the symptoms show which type is indicated. An injection should be given every two to three hours until the patient shows definite symptoms of recovery. One of the striking symptoms is blindness; another ptosis of the upper eyelid. As the toxins are neutralized these symptoms improve.

Professor Amaral has succeeded in crystallizing the toxin but so far has been unable to synthesize it. He knows that it contains carbon, hydrogen, oxygen and zinc. The poison is very complex in structure. In one species of snake Professor Amaral claims to have isolated twelve different poisons, each having an affinity for certain structures of the body. One affects the cardiac muscles, one causes lysis of the white blood cells, one of the red blood cells, another

causes smooth muscle poisoning, one paralysis of the phrenic nerve, one affects the brain and nervous system and one coagulates the blood, et cetera. This coagulation factor is used in the treatment of purpuric diseases. The snakes are obtained from ranches in the interior in exchange for antivenom. The snakes will not eat while in captivity and die in one or two months. More snakes are received at the institute than can be used.

The use of alcohol is not helpful but is injurious in treatment of snake bites as it reduces the resistance of the victim. The bite of a venomous snake seldom causes bleeding because it is a deep puncture of the fangs and the venom coagulates the blood. Non-poisonous snake bites cause bleeding because these snakes have many teeth and they tear the tissues. The black snake is immune to snake bites and will destroy the poisonous snake if in the same enclosure. A poisonous snake will not attack people but non-poisonous snakes do.

The venom is comparable to the parotid secretion of man, it is proteolytic for the carnivorous food of the snake and for the tissues of man. The dose of the antivenom is inversely proportionate to the weight of the patient. Smaller individuals receive the larger doses. Success also depends on the time factor, the earlier the antivenom is given the better. The laity can administer the serum. Only 30 per cent of persons bitten need antiserum but there is no way of selecting this group. The mortality has been lowered from 20 to 2 per cent by treatment. It is very difficult to immunize against snake bites, for it takes three months to produce an immunity which lasts only a few weeks.

The guinea pig is very susceptible to snake poison. A guinea pig is now being crossed with a native pig called "Kova" which is resistant to venom. It is found that the hybrid animal produced by this crossing develops skull changes resembling the "Kova." Dr. Amaral said this indicates that immunity laws apparently follow the Mendelian laws of heredity. He does not recommend the use of South American serum in other countries because of the necessity of strict specificity.

In Brazil the Japanese inhabitants eat snakes as a delicacy. Professor Amaral is doing some research work upon a worm infestation which occurs in Brazil. These worms occur in rodents eaten by snakes and the snakes are eaten by the Japanese. He believes this worm will be found in the Japanese immigrants.

They also have several species of large poisonous toads from which they have extracted a toxin that resembles digitalis in action. The parotid gland secretion of toads is alkaline and its alkaloid is Buffotoxin.

The institute is doing research on the coffee bean. Professor Amaral has demonstrated that the harmful effect of coffee is not that of caffein but another alkaloid which is not yet isolated.

They are conducting research in virus diseases and other infections, such as Rocky Mountain fever and typhus in relation to Brazil.

In the laboratory of Endocrinology, Professor Amaral demonstrated two rats, a male and a female, whose peritoneal cavities had been anastomosed. The male had been castrated. The experiment showed that the excess of pituitary hormone from the castrated male was causing an enlargement of the uterus and adnexa in the female. The uterus occupied both peritoneal cavities. In the eye of the female they had transplanted a piece of the ovary and were able to see with an ordinary magnifying glass this ovary form follicles in the cavity of the eye. He showed a second animal in which the tuber cinereum had been destroyed by cauterization. This animal showed a profuse growth of incisor teeth which had become so long they had the appearance of tusks curled upon themselves. This demonstrated the factor of growth from the tuber cinereum which may be related to the growth factors of the body in general.

In the laboratories we also saw models of phagedenic ulcers which had been cured by the application of plain horse serum, dried and powdered, which is very stimulating for tissue growth. This dried serum may be used in varicose ulcers.

Professor Dr. Joao de Aguiar Pupo, Dean and Professor of Syphilology and Dermatology, showed us through the medical center of Sao Paulo. It is a new building financed by a $2,000,000 grant from the Rockefeller Foundation matched by the State of Sao Paulo. Its teaching facilities are modern in every way. No medical school could ask for finer equipment or better facilities for study. The departments

of Embryology and Physiology are very complete, having models, drawings and actual specimens projected and artificially lighted. A lecture room designed by Professor Edmundo Vasconcelos was the last word in equipment. The entire room was artificially lighted. There were illuminated glass boards which could be used in a dark room. The projecting apparatus was controlled from the operating table and the seats were individually lighted.

The medical course at the University is six years and the requirements for entry are two years pre-medical and competitive examination. Three hundred and fifty apply; only seventy are accepted. Students pay no tuition. Only graduates of this University are admitted to practice. Foreign doctors must take the last three years at the school and also must take the examination in Portuguese. Only naturalized citizens may take the examination.

We traveled by cable railroad to Santos, a town of about fifty thousand and the seaport of Sao Paulo. It was formerly called the white man's graveyard due to ravages of yellow fever and typhus. Modern sanitation has changed all this. A paved road has just been completed connecting Santos with Sao Paulo. Ninety per cent of the world's coffee is transported over the cable railway from Sao Paulo to Santos. This is considered the most remarkable railroad in the world. Trains are taken up and down by counterbalanced cables, three cars up and three down every seven minutes. The construction of this road is a great engineering feat, not only on account of the steep incline but because of the annual rainfall of one hundred and eighty inches which necessitates elaborate watercourses to prevent washouts.

The Orchid Park at Santos has four thousand of the forty thousand varieties of orchids found in Brazil. There were rare varieties of orchids most strange and beautiful.

At Montevideo, the capital of Uruguay, we were received by Dr. J. A. Whitelaw at the Department of Health. He explained their public health set-up, which is most advanced. They have public health stations in all parts of the country where laboratory work and serology examinations are at the disposal of practicing physicians. Tuberculosis and syphilis are under complete control. Formerly 25 per cent of the population were luetic. Since control measures were adopted this has been much reduced. The cost of the program has been defrayed by a one per cent land tax.

The medical societies of Uruguay are organized in a federation of medico-scientific societies. Twenty-three medical journals are sent to all its branches for dissemination of medical literature, of which twenty-one are from the United States. Its own reports and transactions are sent to thirty-five medical institutions in the United States.

The incidence of echinococcus is high. As one doctor expressed it, "A man who comes from the country, wears high boots and has a large liver, may be safely diagnosed hydatid cyst." In treatment of echinococcus cysts of the lung the choice is for a two-stage operation. Daughter cysts occur in the liver but not in the lung. At the Pasteur hospital Professor Alfredo Navarro performed a one-stage operation on echinococcus.

Professor P. Lasnier, at the school of medicine, was experimenting with the possibility of diagnosing carcinoma of the lung from cells found in the sputum. At the University School of Medicine several clinical presentations and papers were given. One advocated the use of folliculin ointment for acne vulgaris and for hypertrichosis with a report of ten cases treated effectively by folliculin ointment 25,000 to 50,000 units.

Cases were demonstrated showing a coincidence of hyperthyroidism with hypopituitarism in undergrowth with delayed ossification, slow dentition, mental retardation and delayed speaking. They discussed the relation of thyroid to ossification while Americans who follow Engelbach believe that the thyroid is responsible. A case shown was a patient with hypothyroidism who received large doses of thyroid and showed premature ossification. This case throws much weight in favor of the American viewpoint.

On the evening of April eighteenth we boarded a river steamer for Buenos Aires, a city of two million people located on the Plate river. The Plate river is forty miles wide at its mouth. The harbor at Buenos Aires is not deep enough to accommodate the largest ocean-going vessels. Buenos Aires is a busy place which has caught the modern trend. Nowhere else have I seen so

many wide boulevards being cut through the business section. When these are completed they will rival the Boulevards of Paris. They have three subway systems. Buenos Aires, as a city, has favorable health conditions. There is no dysentery or malaria. They have one medical center and ten general hospitals, all assisted by the government. We were welcomed by Dr. R. Castex and his associates. Professor Castex in general chairman, holds the chair of internal medicine and is in charge of clinics for all of South America.

We were treated to an array of medical clinics. There were twenty-six papers and demonstrations covering a variety of medical subjects. There was a demonstration of cisternal puncture and encephalography; paper by Dr. Dowling on tumors of the central nervous system; paper by Lanari on the dangers of thorium oxide medication for diagnosis of liver disease; demonstration (Jacobeus's method) of pleural blebs which comes with acute idiopathic pneumothorax; cataract removal by pneumatic forceps; a case of progeria, premature senility with senile type of loss of teeth in a congenital syphilitic boy; bronchographic demonstration of cancer of the lung; lung puncture for diagnostic removal of tissue cells; and a case of obesity whose underlying condition was due to suboxidation due to faulty breathing with improvement from breathing exercises. In a discussion of black cardiacs, x-ray demonstration of bronchial changes in black cardiacs showed they do not suffer from a lack of oxygen in the blood. There is polycythemia and they are worse in the winter. The chief pathological finding is a chronic bronchitis with emphysema. X-ray gives the appearance of: (1) winter tree; (2) spring tree; (3) summer tree, according to the stage of the disease.

Dr. Pollitzer demonstrated his "Diagraphia" which visualizes in the x-ray film respiratory excursion in normal and abnormal lungs, heart, mediastinum and diaphragm. These films were put into a machine which gave them the appearance of a normal expansion and contraction of these organs. Dr. Pollitzer was able to show some lung cavities which contracted and others that expanded while still others showed no change. Its scientific value is not determined.

The intra-arterial injection of acetylcholine for therapeutic uses was demonstrated.

The recommended treatment of intermittent claudication and thrombo-angiitis obliterans is the subcutaneous injection daily of 250 to 750 c.c. of oxygen 95% plus carbon dioxide 5%, twenty days in succession. The injection requires ten to fifteen minutes, under moderate pressure. It is not painful and the gas is absorbed completely in twelve to sixty hours. Body movement facilitates absorption. A patient who could walk one or two blocks now walks sixty blocks without claudication.

We were shown the use of a single large dose of sodium salicylate in acute rheumatic fever when a liter containing 23.5 grams was administered per rectum, 40 drops per minute by Murphy drip.

A lecture on parasitology in Argentina was given by Dr. Greenway. Fifty per cent of digestive disturbances in Buenos Aires is due to tenia saginata which travels from cow to man to cow. Raw meat is the medium. Hookworm and trichinosis are common.

We were shown the use of paper x-ray films for diagnosis of tuberculosis in a general population. Demonstration was given of a method for taking a large number of x-rays in rapid succession. This apparatus can be taken from place to place and chest plates of large groups of people taken in a very short time. In one year 80,000 x-rays of the general population were taken by this method. Thirteen thousand showed tuberculosis, 71 per cent with lesions, and 61 per cent of the 71 per cent with cavitation.

Our medical group visited the municipal hospital, Hospital Muniz. It is a large hospital equipped to segregate contagious diseases. The tuberculosis building is new and beautiful. There is a new department of pathology in which research on leprosy is to be carried on. The chief prepared slides of leprosy bacilli. Diagnostic points on leprosy are: anesthesia to pin prick, falling of eyebrows, alopecia, mask face, bulbous nose and face, pocked skin, etc. In the wards we saw medium and advanced cases, varying from lesions which consisted of atrophy of the subcutaneous tissue to peripheral neuritis to diffuse skin lesions with ulceration and destruction of extremities.

Dr. Biassoti, assistant to Professor Houssey, is a co-discoverer of the importance of the pituitary in diabetes. His experiments on hypophysectomized dogs led to the knowledge that the anterior lobe of the hypophysis is the source of many hormones, among which are those that control carbohydrates, protein and fat metabolism, as well as those that govern growth, gonads, secondary sex characters, et cetera. Biassoti holds that insulin is glycolytic and thyroxin proteolytic.

Biassoti and his colleagues have produced histine insulin to replace protamine insulin. His curves show that its effects are completely comparable to protamine insulin. Chemically it is crystalline insulin plus histine.

Professor Houssey after conducting us through his laboratory gave us a lecture on the hypophysis. Though a very modest individual, he is one of the outstanding men in medicine today. His laboratories are well organized and he is making real progress in his field of research. He has added such to our knowledge of the pituitary gland. He showed us pictures and graphs showing the effect of pituitary on experimental animals. Many of his experiments on the pituitary are carried out in frogs. He stated, "It is easier to operate upon the pituitary in the frog as it can be reached through the mouth and besides the reactions that occur seem to be exaggerated, making it easier to study."

Some of our members visited the clinic of Dr. Gutierrez. He is chief surgeon at the Spanish hospital, an institute supported by a benefit society of 70,000 members, each paying two pesos and up per month. They have free beds, second class and first class rooms. The first class pay ten pesos a day, have a private bath and a bed for relatives in the same room.

Dr. Gutierrez demonstrated the use of epidural anesthesia. He has used this anesthesia in 3,400 cases without a fatality. It is injected into the epidural space, 40 c.c. of a 2 per cent solution of novocaine. This anesthesia is based on the physiologic fact that the epidural space has a negative manometric pressure. This space can hold as much as 200 c.c. of fluid. The dura being attached to the foramen magnum prevents the anesthetic from reaching the brain. The anesthesia extends from the clavicle to the feet, lasts from one and one-half to three hours. The method was first presented by Dr. Pages, a Spaniard, in 1921. He reported forty-one cases. Soon after, he was killed in an automobile accident. In 1931 an Italian surgeon claimed the invention. When Dr. Gutierrez published his report he gave credit to Dr. Pages. Dr. Pages used a 1 per cent solution, which is not strong enough. One must use 2 per cent. Dr. Gutierrez uses it in selected cases, preferably when blood pressure is high. It is a good anesthetic. There is no drop in blood pressure, no headache and no vomiting; it also lasts longer and is safer than the subdural. It requires skill in administration. The needle is introduced slowly; a drop of water is placed in the head of the needle. When the epidural space is entered the negative pressure disturbs the drop. One can also test by trying to inject the anesthetic. If one meets resistance the needle is not in the proper place. When the epidural space is entered the fluid can be injected without any resistance. If one enters the subdural space the needle is withdrawn and the next interspace is tried. Dr. Gutierrez usually injects in the first or second lumbar space. For the new beginner he recommends a small manometer attached to the needle, as this makes it easier to find the space. At first 5 c.c. are injected, then after a five-minute interval, 10 c.c. are injected followed by 20 c.c. a few minutes later. This gives enough anesthesia for a breast amputation or resection of the stomach. Hernia can be done with 25 to 30 c.c.

Dr. Gutierrez has also devised an operation for nephropexy. Most floating kidneys occur on the right side. He stated that the kidney has a space of its own and when this space is deformed you have ptosis. It is possible to demonstrate this space by liberating the hepatic flexure of the colon and turning it toward the midline. The kidney is then shoved back into position. A transverse incision into this space just below the kidney is made. The upper edge of this incision is stitched to the psoas muscle with three or four silk sutures, thus reducing the space to normal size. In ptosis of the kidney the hepatic flexure is usually too low on the colon so he selects a point higher up on the colon, fastening this new flexure by silk sutures through the white band of the colon to the

parietal wall. This is a successful operation. He operated on one case for us and showed us x-rays of several successful cases taken years after the operation showing the kidney in normal position.

Dr. Gutierrez also devised an operation for difficult inguinal herniæ where he transplants the sartorius muscle under the cord and attaches it to the rectus muscle. The muscle is cut through a separate incision at the middle of the thigh, taking care to preserve the nerve and blood supply, bringing it under the cord and fastening it to the external oblique. Two incisions are necessary.

He used Delbet's plaster splints for fractured ankles. They consist of two strips of plaster, one on each side, from below the knee to the sole of the foot, then a figure-of-8 plaster from the lower end of the lateral splints up and crossing the back of the ankle just above the tendo Achillis, then forward over the front of the leg a circular plaster unites the upper ends of the splints. This allows free use of the ankle joint and is a good ambulatory splint.

The BCG is used quite extensively in Buenos Aires as a prophylactic against tuberculosis. American doctors are afraid of this vaccine. It is used extensively in France; about 600 packages are sent out daily from the Pasteur Institute. It is given in milk by mouth at birth.

On April twentieth we visited the Institute of the Benevolent Society of the capital. Professor Ramos did a cesarean section on a patient with contracted pelvis. The patient, a primipara, had been in labor two days. Ether anesthesia was used. The patient was placed in a unique position, the legs being spread and held over stirrups. This allowed the second assistant to stand between the legs. Professor Ramos has good technic. He sutured the peritoneum to the skin before opening the uterus. Dry towels were used within the abdomen. A transverse low incision was made through the visceral peritoneum of the uterus which was reflected up, then a midline incision of the muscle was made. After delivering the fetus with forceps, he injected pituitrin intravenously and allowed the placenta to deliver spontaneously, which it did in ten minutes without much bleeding. The suture line in the wall of the uterus was covered by the reflected peritoneum.

Professor Ramos also operated on a case of multiple fibroids in a young woman twenty-six years of age. She had many large fibroids and several small ones. The uterus was split in the midline and half a dozen fibroids the size of one's fist were enucleated. The uterus was reconstructed using the Reverdin needle. He said she would be able to bear children after this procedure.

There were clinics at the University of La Platte, which is a one hour ride from Buenos Aires. Of special interest was the museum of La Platte. There one finds the most complete collection of early Indian relics found anywhere. They have an enormous fossil collection containing the largest dinosaur skeleton ever discovered.

The hospital, Sanatorio de Llanura e Vincente Lopez y Planes, is located forty miles from Buenos Aires. After a visit to this wonderful institution we were impressed with the prevalence of tuberculosis in South America. The hospital has eight hundred beds and a waiting list of five thousand. Dr. Florencio E. Boneo and staff showed us through the hospital. It is a clean, orderly, efficient institution. Eighteen cases of extrapleural thoracoplasty were lined up before us, all showing splendid results. They showed us fine x-ray studies, a splendid hall of pathologic specimens, long wards of fifty to sixty beds with overhead canopies and spotless white linens. We noted the perfect coiffures of the girls in the beds, their bright eyes, sunburnt complexions and pleasing faces. All of these features together with perfect military discipline made this a model tuberculosis sanatorium. The discipline was perfect, with certain hours relegated to rest, exercise, diet, hygiene, etc. This place is a great credit to Buenos Aires and Argentina. Dr. Boneo demonstrated his own saddle chair for thoracoplasty (Fig. 3).

Our receptions at the American Embassy at Montevideo and at Buenos Aires were particularly pleasant. At Buenos Aires the Embassy overlooks the park system. The buildings, grounds and view makes the White House at Washington look cheap by comparison. The Embassy, formerly the home of a private citizen of Buenos Aires, is owned by the United

States Government. It cost the government one and one-half million dollars.

On April twenty-third we left Buenos Aires by train and arrived at Mendoza, the grape center of South America, the next morning. The trip over the Pampas was most interesting. It is a flat country with grass knee-high and cattle everywhere. No other country can produce cattle with so little effort as Argentina with thousands of miles of good pasture, wide open ranges and plenty of water. The owner has to see his animals only twice, once when the calves have their ears clipped for identification and again when they go to market.

The trip across the Andes is one never to be forgotten. The Christ Monument is in a pass about 13,000 feet high and the descent on the West slope is very steep. I counted one hundred thirty-two hairpin turns from the monument to the river below. Some of our party felt the effect of the altitude and we were all glad to get down. It is a very dangerous trip. We traveled by automobile on a one way road, starting at 5:00 A. M. and reaching Santiago at 10:00 P. M., a long, hard, interesting journey.

Santiago is a beautiful city situated in a valley at the foot of the Andes. The medical work is of high grade. Buildings and operating rooms are antiquated. Coal stoves were used for heat while ether was being administered nearby. At the Institute of Cancer we saw exceptionally high-class work by Dr. Leonard Guzman. They have one and one-half grams of radium and use it to the exclusion of surgery in carcinoma of the cervix. His cures run from 25 per cent to 65 per cent according to the degree of involvement. They follow the French school and apply small doses over a long period of time, rather than massive doses for short time as is the usual practice in the United States. Ten or fifteen milligrams are left in the uterus for as long as three weeks, being taken out every other day, cleansed and re-applied. Dr. Mardonez is director of the medical school, which was established one hundred years ago.

We went by train to Valparaiso, the seaport of Santiago. It was formerly the largest city of Chile but now Santiago is twice the size of Valparaiso. The medical work of Valparaiso is of high character in spite of dilapidated buildings and poor equipment. As Dr. Munich expressed it, "We have stopped apologizing for the looks of the buildings and call attention only to our work. After seeing the old ampitheater in Vienna where Billroth and Von Eiselberg did

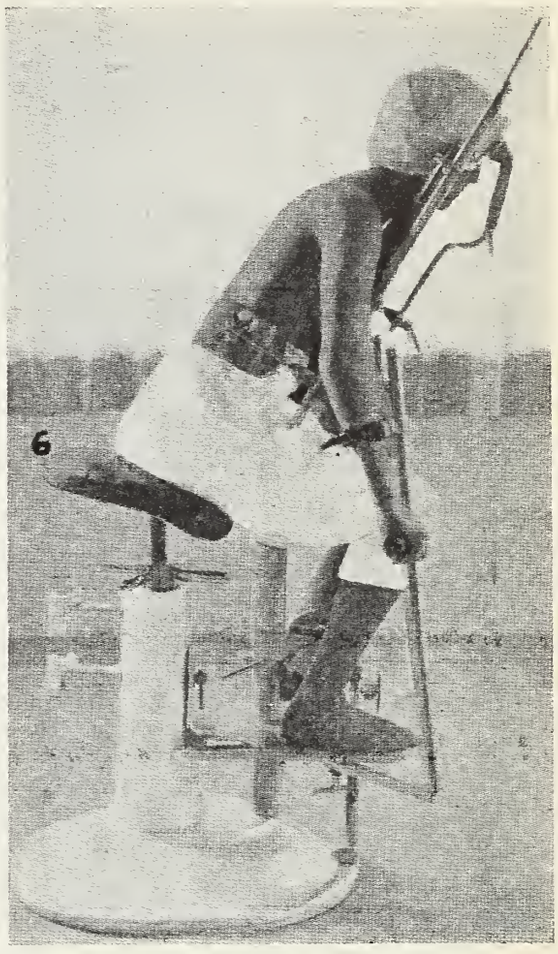

Fig. 3. Saddle chair for thoracoplasty designed by Dr. Florencio E. Boneo.

such brilliant work we have decided that it is not the buildings that are important."

Dr. Munich and staff had a full morning of surgical cases, including cervical rib, diverticulum of esophagus, acute hemorrhagic pancreatitis, goiter, thoracoplasty and gastroenterostomy for hourglass stomach due to stricture. Teratoma of the testicles in which a positive Aschheim-Zondek test proved the diagnosis.

The prevalence of lues can be judged by the statement of Dr. Reed, who said, "With every clinic of ten patients there are eleven cases of syphilis, if you include the professor."

Dr. Marrianna's test for Addison's disease is based on the fact that morphine plus glucose alters the blood sugar curves. In Addison's after morphine, the blood sugar falls; in normal cases the blood sugar rises.

The San Agustin and Vina del Mar Hospitals

were erected sixty-four years after Columbus discovered America. Acute infectious hepatitis is a very common disease in Chile. They had fifty cases at the hospital this spring. Twelve per cent of all admissions are affected with this disease, the cause of which is unknown, but may be a spirillum. Asthma is treated by intravenous injections of 20 per cent 90 proof alcohol in glucose water solution, first dose of 5 c.c. being later increased to 10 or 20 c.c.

After a delightful banquet given by the medical profession and city of Valparaiso, we boarded the Grace line, Santa Clara, and sailed up the west coast of South America. The captain said he was always glad to leave the harbor of Valparaiso on account of his fear of earthquakes. The voyage up the west coast was the most interesting of our journey.

The west coast is influenced by the Humboldt current as much as England and the Scandinavian countries are influenced by the gulf stream except that the Humboldt current is cold, coming from the Antarctics, while the gulf stream is warm, coming from the Equator. The Humboldt current strikes the west coast of Brazil south of Valparaiso and follows the coast up as far as the middle of Peru where it turns toward Hawaii and is joined by the Japanese current. This cold current causes the moisture from the trade winds to fall several hundred miles out to sea, and on the coast of Chile and Peru they only have rains about three times a century. This happens only when the current for some reason changes its course. On account of the Humboldt current the west coast is dry and cool in spite of the blazing tropical sun. The average temperature of Lima, Peru, is from 65 to 75 degrees the year around.

The bird life along this coast is most interesting. There were millions of guana birds resting on the water, and the sea was alive with fish which came to the surface so that one could see their fins churning the water. Thousands of birds feeding upon these fish would drop like spears into the water. We also sailed among many schools of seal and porpoise.

At Lima we saw ruins of the old ancient Aztec civilization. Their capital city is Cuzco, located on a plateau in the Andes.

On May eighth we visited Guayaquil, a city without rain. It is the principal center for panama hats, which, contrary to the popular belief, come from Ecuador. We were courteously received by the President of the University and several members of the faculty. The buildings are quite antiquated and evidence of their economic limitations is visible on all sides. We were driven to the city hospital, which is also the University hospital. There were more than one hundred patients and visitors at the entrance waiting admittance to the out-patient departmen. They filled the entrance corridor. The hospital wards contained about fifty to sixty beds. I asked one of the doctors what kind of diseases they treated. He promptly replied, "Syphilis." We learned that they also had cases of bubonic plague and a few cases of yellow fever at the time of our visit. A doctor from the United States Health Service had just been there to make the diagnosis. Some of our doctors were shown bacillus pestis out of a fresh case.

From Guayaquil we sailed to Panama city. As we passed through the canal this interesting project was explained to us by a professional lecturer furnished by the Grace Line. Colon on the Atlantic side is a free port and enormous cargoes from all parts of the world were being transferred there. We spent one day in Havana and then journeyed back to New York.

The South American trip was very interesting and well worth the time and money spent.

* * *

In addition to the doctors mentioned, hosts of other distinguished physicians gave us clinics and demonstrations, for which we are grateful We were received by the public officials of all countries visited and we appreciate this honor.

I am indebted to the members of the party for the use of their notes, particularly to Dr. J. H. Barach, who consolidated them.

CONGENITAL MEGACOLON TREATED BY DAILY HOT IRRIGATIONS OF NORMAL SALINE SOLUTION AT 115 DEGREES*

AARON FRIEDELL, M.D.
Minneapolis, Minnesota

ACCORDING to Ruhrah,[16] Billard in 1820 described a case of congenital megacolon and called it sclerosis of the colon; Parry reported a case in an adult in 1825; Hirschsprung gave this malady the name megacolon in 1880 and published his classical description in 1888. Since then many cases and summaries of reported cases have been published. The summary by Judd and Thompson[10] in 1928 includes sixty-five reported cases.

According to Rankin, Bargen and Buie,[15] Hirschsprung defined the disease as "congenital, high grade dilatation of the colon with thickening of all its tunics, especially the tunica muscularis, and retention of large quantities of fecal matter." To date this definition is accepted as it was when it was first published.

Rankin, Bargen and Buie[15] list twenty-two hypotheses concerning the etiology of megacolon. They reduce these hypotheses to a summary under three headings, namely: congenital defects, obstructive processes (due to either anatomic conditions or to disturbances in the nervous mechanisms), and infectious processes. In most cases the pathogenesis is mixed with the several etiologic factors often combining to produce the condition of megacolon.

In the realm of treatment many recommendations are made by various authors. The most successful form to date is sympathectomy, first reported by Wade and Royle[18] in 1927. However, in this paper a suggestion is made for treatment employing mechanical and thermal stimuli in a simple form. Although this form of treatment is slow in achieving its results, yet because it carries none of the risks and complications of a sympathectomy, it deserves further study and trial.

The following three cases were so treated with good results.

*From the Department of Pediatrics, University of Minnesota.

Case Reports

Case 1.—R. F.,* male, three and a half years old, was diagnosed congenital megacolon when but five months old. He had medical care at various times, dietary regime, and hospitalization, but up to the time of this last admission he had little or no relief.

On admission to the University Hospital on May 16, 1931, his constipation was quite marked, more so than at any previous time. At irregular intervals he had attacks of nausea and vomiting, accompanied by marked abdominal distention. He was rather pale and weak. His abdomen protruded and was unusually large. It measured 64 cm. in circumference. His weight was 14,500 gm. The physical examination was essentially negative except for his very large abdomen. The urine was normal. The blood showed an anemia: hgb. 55 per cent, r.b.c. 3,800,000. The differential was normal. The blood calcium was normal. The Wassermann was negative. During the first three weeks he was given an abundant diet, also iron and cod-liver oil, enemas and purgatives and blood transfusions, but there was no improvement.

At the time this form of treatment was instituted, this boy was actually failing. He was pale and weak and could not sit up to take nourishment. Even though he was fed he could not take much nourishment and he had emesis frequently.

Sympathectomy was considered during the first three weeks, but as the patient's condition was becoming more and more serious this could not be done. On June 9, treatment consisting of a hot daily colon irrigation through a specially designed rectal instrument (Fig. 1) permitting a controlled inflow and outflow, was instituted. Normal saline solution was used at 115° F. The treatment lasted from thirty to ninety minutes at first, depending upon the response of the patient. It never lasted less than twenty minutes, but it lasted longer if necessary, until the saline returned clear repeatedly. Several gallons of solution were used at one time. The solution was prepared at the bedside by dissolving the required amount of salt in a gallon of hot water. These irrigations were given slowly in order to avoid distention. In a few days this patient showed signs of recovery and improvement. His listlessness became less marked, he started to take an interest in things about him, and to take food. In ten days he

*A report of this case was presented to the American Academy of Pediatrics at its annual meeting in Minneapolis in October, 1934 (Jour. Pediatrics, 5:733, 1935).

started to sit up and later to stand up. On August 17 he was allowed to be up and around.

The following excerpts from the x-ray reports by Dr. L. Rigler indicate the improvement in the condition and size of the colon.

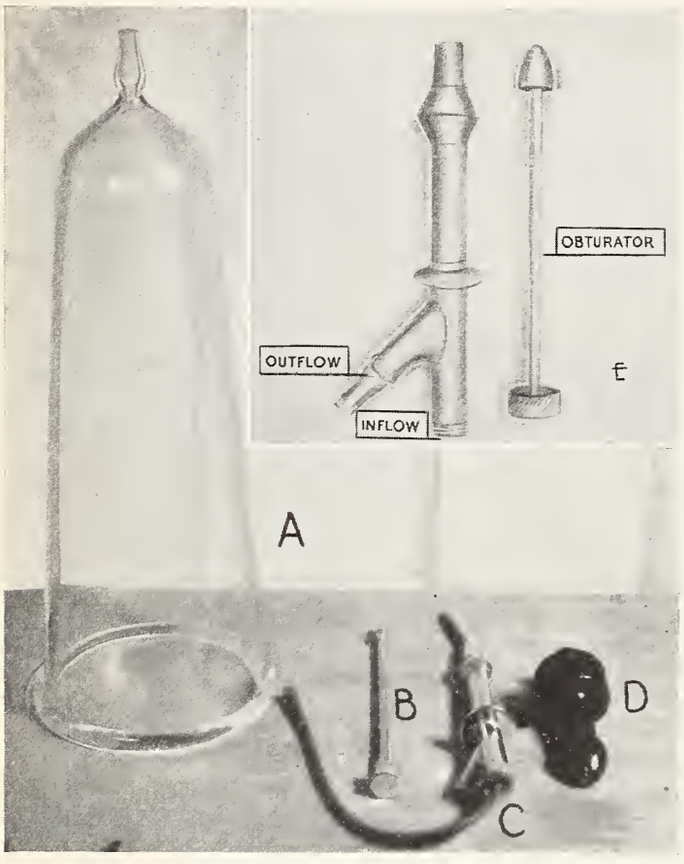

Fig. 1. Apparatus including (*A*) two gallon flask; (*B*) longer irrigator; (*C*) catheter, large size; (*D*) Austin irrigator, small size; (*E*) rectal irrigator.

May 22, 1931 (before treatment) . . . "Enormous colon. On account of the marked distention, only the rectum and part of the sigmoid were filled with 1,500 c.c. of barium sulfate. Conclusion—congenital megacolon." (Fig. 2.)

September 25, 1931 (after four months' treatment) . . . "Marked diminution in size. Caliber is two-thirds to one-half of what it was previously, peristalsis well demonstrated and much more marked than normal. Conclusion—megacolon diminishing." (Fig. 3.)

November 4, 1931. . . . "Further decrease in the size of the colon." (Fig. 4.)

This patient was discharged on December 9, 1931, his mother being instructed how to continue the irrigations at home if needed. The mother continued to give him irrigations at irregular intervals for eight months. On June 29, 1937, this boy was fine, had no more treatments and was having normal stools. He was as normal and as active as other boys nine years old, but his abdomen was still larger than the normal.

Certain observations were made on this first case and checked several times. After but a few minutes of treatment, marked evidence of peristaltic activity was frequently noticeable through the abdominal wall. These waves were very well shown by motion pictures (Fig. 5). To the palpating hand at such times the sensation was similar to that of the contracting uterus during a pain. We noticed at the same time that the outflow had ceased and yet frequently the outflow tube pulsated or jerked. This suggested that possibly the rectum in this case contracted in a region somewhat higher than the sphincter. To the palpating finger this was rather vague, though we were inclined to interpret the muscle rigidity that was felt high up in the rectum as probably capable of preventing an outflow with the outflow tube pulsating. We, therefore, made up a longer irrigator (Fig. 1) and with its use the outflow was better.

Case 2.—Anthony W., male, aged five, was recognized as having congenital megacolon in early infancy, and was admitted to the Minneapolis General Hospital three times. His first admission was on March 21, 1933, when he was fourteen months old. X-ray on March 23rd corroborated the diagnosis of megacolon. He had marked constipation and abdominal distention. The bowels did not move without enemas and he had frequent attacks of pain in his abdomen usually accompanied by listlessness, nausea and vomiting. Repeated x-ray studies corroborated the diagnosis of megacolon. All other findings were negative. The last hospital admission was on August 23, 1936.

X-ray studies on September 9, 30, October 9, and 19, all taken before this method of treatment was instituted, showed no improvement. X-rays January 6, February 10, March 12, 1937, during this treatment, show improvement.

General improvement was noticed a few days after treatment was instituted and was continuous. His general appearance became better, his appetite improved, pain disappeared, the abdominal distention became less marked and he became much more active.

After four months of this treatment a complication became apparent in that his sphincter became gradually more and more spastic though apparently quite normal at the beginning. This spasticity increased and even caused pain on the passage of the rectal irrigator. Dr. W. A. Fansler dilated the sphincter manually under gas anesthesia and relieved the spasticity. His stools have been normal for over ten months.

Case 3.—Emmett C., male, three and one-half years of age, was diagnosed as having congenital megacolon in early infancy. He had marked constipation with frequent attacks of pain, nausea, and vomiting. His abdomen was large and the distention became aggravated quite often. At the time of admission to the Minneapolis General Hospital, January 13, 1937, his complaint

was an upper respiratory disturbance with middle ear involvement. After that cleared up a complete study was made of his case. The diagnosis of megacolon was corroborated by x-ray examination. He was treated by hot saline irrigations with good results. His stools became normal early in May, and he was discharged May 21, 1937, as improved.

Fig. 2. Large colon.

Fig. 3. Colon size reduced.

Fig. 4. Colon size more reduced.

The last two patients were taught abdominal exercises after the stools started to become voluntary; the exercises probably contributed some benefit.

Treatment of megacolon by hot irrigations must not be hurried. It might be better to suspend the treatment entirely than to hurry it. This method of therapy attempts to establish a better coördination between the sympathetic and parasympathetic nervous mechanisms of the colon which have been out of harmony or have probably never been established. But this mechanism has a tempo of its own which cannot be speeded up suddenly. Hurry or rough handling will frustrate our efforts, aggravate the condition and may even produce shock. We have observed more or less reaction every time we tried to rush the treatment or allow over-distention. At one time our first patient actually showed symptoms of shock when we produced marked distention by allowing a great deal of fluid to be retained. The need for gentle handling of the colon can well be corroborated by the physiologist,[3] surgeon[9] and internist.[7] Erlanger[3] showed experimentally how rough handling of the intestines produces shock. Homans[9] states that "shock is caused principally by prolonged handling and mishandling of tissues . . . particularly within the abdomen or thorax." Gardner[7] states that "the giving of a large test enema may reproduce the patient's symptoms by increasing intracolonic tension." The importance of gentleness and taking plenty of time cannot be overemphasized.

The work of Kappers[11] and Alvarez[1] further

Fig. 5. (*A*) Large abdomen; (*B*) irrigator in position, showing peristaltic waves.

emphasizes the importance of the time element in the stimulation of the various parts of the alimentary canal, that the rate of conduction is slowest in the lower intestinal canal. Both of the above mentioned authors state that "the visceral regions keep a primitive type of nervous organization; that the plexuses of Meisner and Auerbach have a conduction rate similar to that in the ganglionic plexus of Coelenterates (20 cm. per sec.)."

The three patients here reported have responded to our efforts to establish normal bowel function. The rationale of this treatment can probably be explained as based on the following considerations:

1. Biologists have observed that tropical heat affords the organism a better opportunity for readjustment and evolutionary changes, as noted by Harold H. Plough and Phillip L. Ives.[14] One wonders, therefore, if under the influence of this heat treatment the colon may not be afforded

a more favorable opportunity for peristaltic activity and in time even reduce in size because of such activity.

2. Garbat and Jacobi[6] show that hot saline in the upper rectum stimulates the liver, an important detoxifying organ, to greater activity. They have demonstrated that 150 c.c. of one of several hot solutions start the flow of bile in a very few minutes and the flow may last over one hour.

3. Okay[13] found direct relationship between peristalsis and increased circulation of the blood in the bowel wall.

4. Freyer and Gellhorn[5] show that high temperature above 104° F. stops parasympathetic action and suspends the production of acetyl choline, but it does not stop sympathetic action.

5. Sir Thomas Lewis[12] shows that the sympathetics are relaxed at a temperature between 43° and 45° C. or 110° and 113° F. and that the response to the above mentioned heat is similar to the response of a local anesthetic. By using hot saline raised to 115° F. we probably overcome the undue tension that may be present in both the sympathetic and parasympathetic control of the colon. Under this comfortable heat both factors are probably afforded a period for activity with its handicaps temporarily allayed.

6. Gardner[7] showed that mechanical distention of the upper rectum may produce symptoms of severe intoxication, which immediately disappear as the pressure is released. We observed similar occurrences in our cases whenever distention occurred. On one occasion in particular, as mentioned above, there was marked reaction, almost shock, and that was relieved with the gradual emptying of the lower bowel.

Conclusions

1. Three cases of congenital megacolon were treated with hot daily irrigation of saline at 115° F. with good results.

2. The method above described, because of its simplicity and absence of risk, is worthy of further study and trial.

3. From this small series no claim can be made that all patients with megacolon can be cured by hot colon irrigation. No damage, however, can be done by trying this method first, and those ultimately requiring a sympathectomy will be benefited and be better prepared by such irrigations.

COMPRESSION FRACTURES OF THE SPINE*

W. W. NAUTH, M.D., and P. A. MATTISON, M.D.

Winona, Minnesota

THIS paper is presented from the experience and observation of the general surgeon rather than that of an orthopedist and we hope that it will be so considered during the discussion which may follow.

Of a total of 886 fractures of all kinds taken care of in our group since 1933, thirty-four or approximately 4 per cent were compression fractures of the vertebral bodies. Of these, two involved the cervical, twelve the dorsal and twenty the lumbar vertebræ.

This 4 per cent is somewhat lower than the 6 per cent reported by other surgeons who take care of more than the average number of fractures encountered in general practice.

Due consideration has been taken in the series of vertebral body anomalies and abnormalities, in order that such may be ruled out. Among these changes in shapes and contour of the vertebral bodies, which are apt to confuse the surgeon and roentgenologist, may be mentioned the following:

1. Normal variations
2. Postural changes
3. Anomolies of development
4. Inflammatory changes
5. Changes in bodies due to intervertebral disc injuries
6. Metabolic changes
7. Malignancy

The diagnosis in all of our cases has been based on the history of a definite injury, with definite symptoms, x-rays before and after reduction, and follow-up x-ray studies.

Until a few years ago perhaps 75 per cent of compression fractures of the spine were overlooked by the average practitioner unless the patient complained severely of his back following injury, or had an associated paralysis which prompted x-ray studies. Many of these patients were left with permanent back disabilities.

In many instances no x-ray studies of any kind were made or when made were taken only in the anterior-posterior position. Anterior-posterior and principally lateral studies are essential in the diagnosis of compression fractures, even following trivial injuries.

While the most important part in the diagnosis rests upon x-ray findings, it is also true that a carefully taken history of the modus operandi of the injury is equally important. Jack-knifing injuries such as falling backwards, landing in a sitting position, or driving under a low bridge while sitting on a wagon, or landing in an upright position with knees extended, are definite reasons to suspect vertebral body fracture, which call for thorough x-ray study of the entire spinal column regardless of the location of pain.

Four of our cases were fractures in patients taken care of in other well appointed hospitals within one week to six months following their original injury, in which only anterior-posterior x-rays were taken and the fractures missed. Several of our cases have been associated with fractures of the os calcis. Because fracture of the os calcis is frequently produced by the individual landing in an upright position, compression fracture of the spine is always a possible complication and should be suspected and investigated.

A case in point is that of a man who walked into an open pit, landing, after a drop of about 20 feet, in an upright position, with knees extended. When brought to the hospital he was in severe shock, with a fracture of the humerus, radius and ulna, a badly comminuted fracture of the upper end of the tibia and fibula, and a fractured os calcis. Owing to his complaints of these severe injuries, he complained very little about his back. Not until months after, when he was allowed to be on his feet, did he complain to any great extent about his back. X-rays taken at this time revealed severe compression fractures of the first and second lumbar. Results of treatment for his other fractures were satisfactory, but the man will always be unable to work because we had overlooked a compression fracture of his spine which, without question, if diagnosed

*From the Winona Clinic, Winona, Minnesota. Read before the annual meeting of the Southern Minnesota Medical Association at Winona, Minnesota, August 11, 1937.

and properly treated at the time of injury would have made him a useful member of society. The modus operandi of his injury should have prompted us to look for a compression fracture of the vertebra.

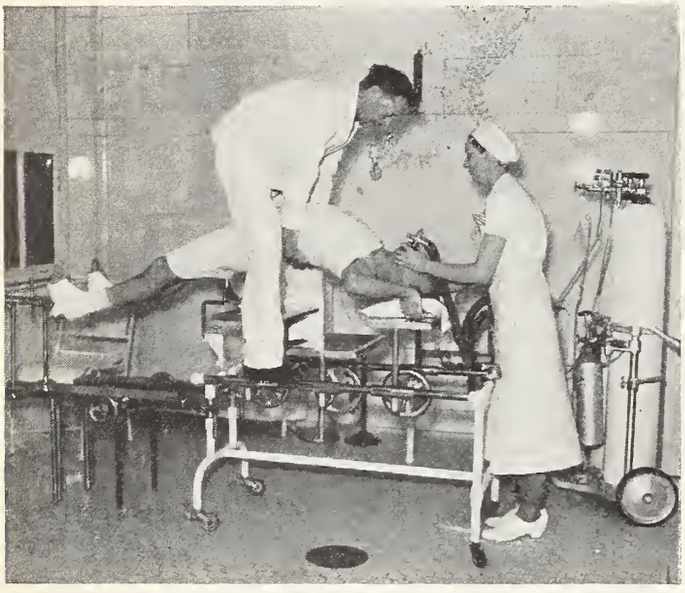

Fig. 1. Method of reduction.

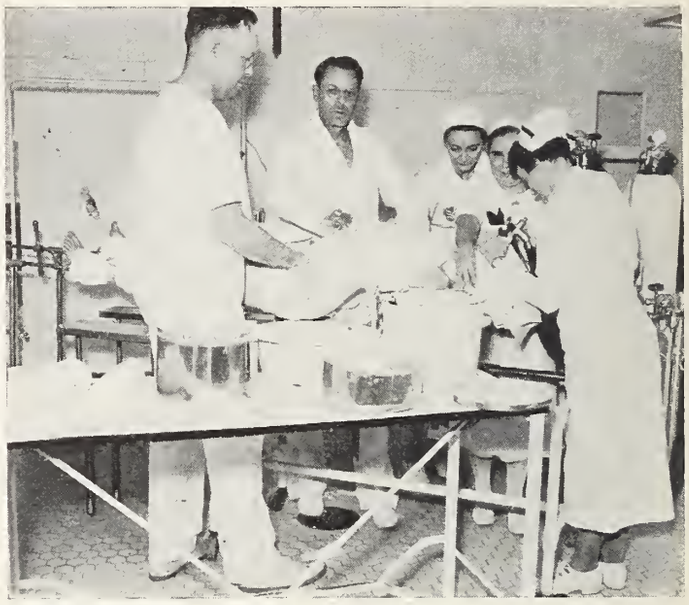

Fig. 2. Patient hyperextended on Magnusen jack. Buttocks and shoulders supported by table. Plaster cast applied.

Another case in point was that of a man who dropped into a river bed in a standing position, then falling against some piling sustained five rib fractures and a fracture of the lower end of the tibia. He was in severe shock when brought to the hospital. Within twelve hours, he developed a traumatic pneumonia and was desperately ill. An anterior-posterior plate was taken of his chest to corroborate our diagnosis of pneumonia and chest injuries. This plate revealed what was reported by the hospital roentgenologist as an arthritic process of the twelfth dorsal vertebra. No lateral studies were made at this time in spite of this report, because following his recovery from pneumonia and other injuries, he made no complaint about his back. [Subsequent x-ray studies, however, did reveal a definite fracture.]

These were early cases which taught us important lessons, and I dare say that we have missed no compression fractures since that time. Multiple injuries to an individual should always call for x-ray studies of the spine.

In our experience and observation besides x-ray findings and the modus operandi of the injury, one of the most important symptoms and points of diagnosis is abdominal pain and rigidity. In none of our cases have we failed to note this symptom commensurate in degree to the severity of the injury to the vertebra involved.

Visceral injuries following an accident have symptoms similar to those found in compression fractures, namely, abdominal pain and rigidity. However, in visceral injuries there is also localized tenderness over the organ involved. In compression fractures with abdominal pain and rigidity, there is as a rule no localized tenderness.

In our series of thirty-four cases, we had two cases of complete lower extremity and visceral paralysis with full recovery. These cases were treated by hyperextension, body cast, and traction followed by braces. Two patients with paralysis, prior to this series, on whom we did laminectomies, did not do so well. One died without recovering, about one year later, the other, while he recovered somewhat, is a wheelchair case for the rest of his life.

It is our belief from our experience that, since the average surgeon is not a neurologist, he is unable, when a back injury with paralysis presents itself, to make a diagnosis as to whether the cord is merely compressed or actually severed. We have not used the Quackenstedt test, therefore, do not know its relative value in settling the question. Edema and hemorrhage in and around the cord rather than a true blocking by bony displacement may confuse and render valueless the Quackenstedt test, except to those who have had considerable experience in its in-

terpretation. Key and Conwell recommend reduction by manipulation and hyperextension in all cases before making the Quackenstedt test. According to the experience of surgeons relying principally on the extension methods for reduction and recovery, there is only a small percentage of cases in which laminectomy is indicated.

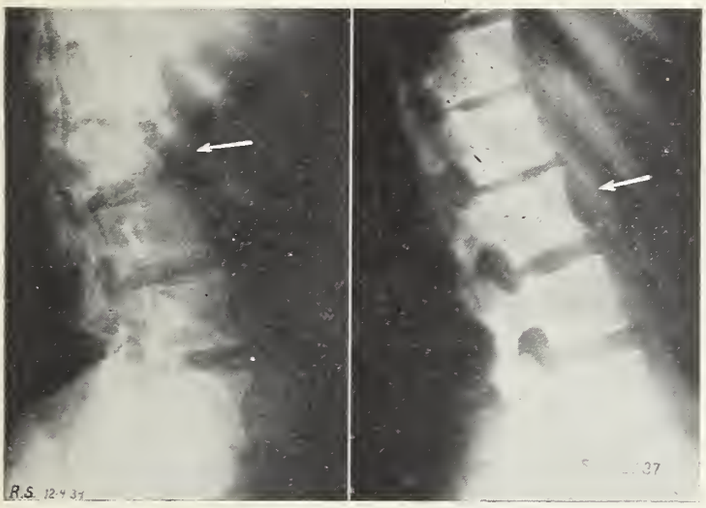

Fig. 3. Compression fracture of second lumbar vertebra with visceral and lower extremity paralysis. (a) Before reduction. (b) Eleven months later.

One of our patients with a fracture of the second lumbar, developed, on the day following his injury and reduction, a paralysis of the entire left arm. X-ray studies revealed no injury to any of the cervical vertebræ. We assumed that this paralysis was caused by hemorrhage and pressure in the cord, described as hematomyelia by Dr. Hammes. This patient obtained full recovery of his arm within three months. We had one case of cervical body fracture with paralysis of the left shoulder and arm with full recovery following traction and cervical brace.

Treatment.—Many methods of reduction and treatment have been used successfully as long as hyperextension was the main factor in reduction and retention. Among these methods are the Magnusen jack, the Allen reduction table, the hammock suspension method, and the symphysis chest position with the patient face down. Manipulation in this position by a sudden sharp thrust downward at the point of injury is often attended by an audible sound when the impaction is reduced. This treatment is followed by a carefully applied body cast, with the patient in the hyperextended position.

In two of our cases with the chest-symphysis position we had considerable worry, because of the patients difficulty in the breathing. Both became cyanotic and had to be turned before the application of the cast was completed. We, therefore, adopted the following method which we have not seen described: The patient is

Fig. 4. Compression fracture of first lumbar vertebra. (a) Before reduction. (b) Eleven months later.

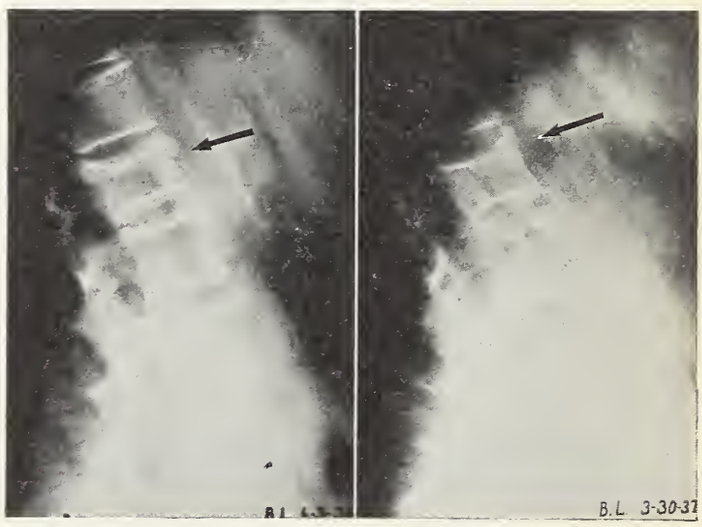

Fig. 5. Compression fracture of first lumbar vertebra. (a) Before reduction. (b) Ten months later.

anesthetized lying flat on his back, the table is straddled by the operator who places his arms with locked fingers under the patient's back at the point of injury, slowly suspending the patient until the buttox and shoulders are free from the table. He then gives a sudden sharp upward thrust of the body, then by dropping his locked hands he intercepts the drop of the patient and holds him in this position until the Magnusen jack is placed under him. The cast is then applied. We have had no respiratory complications with this procedure and have had equally good results. All of our non-paralyzed cases, regardless of the degree of compression,

if reduced, are permitted to be up and about in from one to two weeks. The cast is kept on for three months. Then a well-fitting Taylor brace is applied, made always from a plaster model of the patient in the hyperextended position. Such braces always fit perfectly.

Prognosis.—Prognosis is essentially very satisfactory if properly treated. All of the patients in this series, including the two with paralysis, are well without major complaints, able to work and carry on practically as well as before injury. We think this justifies a good prognosis for the majority of patients who sustain a compression fracture of the vertebræ. Both compensation and private cases as a matter of fact have given us less trouble than other fractures as a whole.

A CLINICAL TEST FOR PREGNANCY*

D. E. MOREHEAD, M.D., F.A.C.S.
Owatonna, Minnesota

INTEREST in the possibility of securing an accurate intradermal test for the diagnosis of pregnancy has again been stimulated by the recent report of Gilfillen and Gregg[4] on the intradermal use of Antuitrin-S. The advantages of such a test, if accurate, are self-evident.

Zondek[8] and Aschheim[1] showed that there was present in pregnancy urine a large amount of gonad stimulating hormones. It is not known who originated the idea to utilize this substance in some way for the diagnosis of pregnancy; however, Porges and Pollatschek[6] were probably the first to report work of this kind.

The pregnancy urine gonadotrope was originally considered to be of pituitary origin, so that it is not surprising to find the above investigators as well as subsequent workers using anterior hypophyseal extracts for the same purpose. Deutsch[2] in 1929 and Strauss[7] in 1930 reopened the study, as did Dowell[3] in this country in 1934. The results from all these sources were considered to be of no value, due to the high percentage of error. Gruskin[5] in 1936 attempted to solve the problem by using a placental extract as an intracutaneous test. This was similarly found to be inaccurate.

It is not surprising, however, that failure followed these attempts since pituitary extracts containing the gonadotropic hormone also contain large amounts of extraneous matter. This would be true also of placental extracts.

Antuitrin-S was used by Gilfillen and Gregg[4] in their work. They reasoned much the same as their predecessors that the pregnant subject having a high concentration of the anterior pituitary-like hormone present should be "desensitized" or "immune" to its intradermal administration; further, that the reverse should obtain in the non-pregnant state.

Antuitrin-S contains two milligrams of solids per cubic centimeter. One milligram is the active hormone and the remainder is extraneous, inactive material of a non-protein nature. The potency is adjusted so that one milligram in 1 c.c. of solution contains 175 rat units of the hormone. The solution is adjusted to a pH of 7.1 or 7.2, this being the pH of optimal preservation of the hormone. The only protein in solution found by test is that directly attributable to the anterior pituitary-like hormone. That this hormone is protein in nature is undoubted although total nitrogen runs around 0.9 per cent. (The average protein is from 14 to 16 per cent nitrogen). Furthermore, Antuitrin-S varies negligibly in solid content, that is to say, the protein content is constant. If we may now theorize we might suspect that the hormone is an aggregation of complex protein molecules possibly resembling the polypeptides.

In this paper I am reporting pregnancy tests in 100 cases, not all of pregnancy, made with Antuitrin-S manufactured by Parke, Davis and Co., and Follutin manufactured by E. R. Squibb and Co. Sixty-one of these cases are my own and thirty-nine were run by Dr. James Morrow of Austin, Minnesota. Neither one knew the other was making similar tests. Dr. Morrow was kind enough to turn over his cases to me to be reported at this time.

Dr. Morrow's series includes two post-partem cases, two cases where the menopause had set in,

*Read before the annual meeting of the Minnesota State Medical Association, Saint Paul, Minnesota, May 4, 1937.

and several questionable cases of pregnancy which were checked with the Friedman test. In his series Antuitrin-S affirmed the presence of pregnancy in four cases in which the Friedman test was negative. There were eleven cases of pregnancy positive both with Antuitrin-S, and the Friedman test. Six cases affirmed the absence of pregnancy while the Friedman test was positive. Two patients past the menopause gave negative results with both the Antuitrin-S and Friedman tests. Two patients sixteen and twenty-seven days post-partem respectively gave a positive Antuitrin-S reaction. Antuitrin-S was positive for pregnancy in three patients who were not pregnant.

In my own series I tried to adhere to the rules laid down by Gilfillen and Gregg, that is, to read the test in one-half hour and again in one hour. I found that I could not depend on the test to react in one hour's time. I found that the test might require six or eight hours to react, showing an absence of pregnancy, so that a reading in a shorter period of time would lead to an erroneous diagnosis. Antuitrin-S and Follutein were used, one to check against the other. There was one case of ectopic pregnancy where Antuitrin-S and Follutein both showed pregnancy present. Operation confirmed this diagnosis. In one case where an ectopic pregnancy was suspected the test showed pregnancy absent after six hours. The patient was not operated upon and time has proved that pregnancy was absent. In six patients known to be pregnant, both Follutein and Antuitrin-S showed an absence of pregnancy. On repeated tests they both showed pregnancy absent. The remainder of the known pregnancy cases were confirmed with both Follutein and Antuitrin-S. In thirty non-pregnant patients the test showed an absence of pregnancy and none of the tests showed pregnancy when it did not exist.

Summary

From my observations I would say the test is more accurate if used to diagnose the absence of pregnancy. Further study must be made to determine why some reactions fail to confirm the presence of pregnancy.

CASE REPORT

CHYLURIA*

GEORGE B. EUSTERMAN, M.D.
Rochester, Minnesota

A WHITE, married woman, fifty-nine years of age, entered The Mayo Clinic on November 16, 1936, with the complaint that one morning while she had been collecting a specimen of urine for periodic urinalysis by her family physician she had noticed that it had the appearance of milk. The patient had had the urine examined on an average of four times a year for the past ten or twelve years but this was the first urine of abnormal appearance, to her knowledge. On four successive days before admission at the clinic the urine first voided, usually about 6:30 a. m., was milky, but all urine passed thereafter remained clear. Exclusive of chronic senescent arthritis of low grade, affecting one knee, and mild digestive disturbances after eating too heartily of rich foods, the patient made no other complaint. Recently she had lost 8 pounds (3.6 kg.) as the result of voluntary dietary restrictions.

Physical examination gave essentially negative results. The blood pressure and temperature were within normal limits. The urine had a decidedly milky appearance. It was necessary to convince the laboratory technician that it was not milk before she would undertake examination, for a week previously a young mother mistakenly had sent a small bottle of milk for examination instead of the child's urine which had been collected in a similar bottle. The specific gravity was 1.023; albumin and sugar were absent. Microscopic examination disclosed a few erythrocytes and about 20 leukocytes per low power field. The presence of chyle was determined by further chemical and microscopic examination. A catheterized specimen, obtained the same day, was free of erythrocytes and leukocytes. The concentration of blood urea was within normal

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the meeting of the Southern Minnesota Medical Association, Winona, Minnesota, August 11, 1937.

limits. There were no significant changes in the ocular fundi. Roentgenographic examination of the urinary tract, including an intravenous urogram, roentgenographic examination of the organs of the thorax, as well as roentgenoscopic examination of the stomach and duodenum, failed to disclose evidence of any abnormality.

The patient returned a month later for further examination of the urinary tract in order to determine whether the chyle issued from one or from both kidneys, or from a lower level, and whether there was a fistulous communication with the lumbar lymphatic structures. Whether or not such communication was demonstrable, it also was decided at this examination to inject the contrast media under pressure while doing retrograde pyelography because this procedure had been known to interrupt such a fistulous communication, with permanent disappearance of chyle from the urine. Cystoscopic examination was carried out early in the morning, before the patient had voided or had assumed an erect position. Clear urine was found to issue from the meatuses on both sides. The first catheterized specimen from the left renal pelvis appeared to be clear but the second one was slightly turbid and milky in appearance. This specimen also clotted soon after its collection. Chemical and microscopic examination of this milky specimen revealed the presence of chyle but absence of filaria and bacteria. Retrograde pyelography disclosed that the outlines of the right renal pelvis, calices and ureter were normal. The pelvis of the left kidney and ureter also appeared to be normal. Beyond the tip of the lower calix apparently there was some small extravasation but evidence of a lymphatic communication was lacking. The contrast media was injected under pressure and there has been no recurrence of the chyluria up to the present time.

Under the title "nonparasitic chyluria" two previous communications dealing with cases encountered in the clinic have been made. The first one was made by Allen in 1933, who reported two cases, and the second by Wakefield and Thompson, whose article appeared July, 1937, in the *Journal of Urology*. This latter article dealt with five cases encountered in the clinic up to January, 1937, and included the cases reported by Allen and the case presented herewith, briefly summarized. More than 100 cases of nonparasitic chyluria have been reported so far in the literature.

A few features of clinical interest, as they pertain to this case, may be discussed. In the first place, the possibility of parasitic origin of the chyluria cannot be ignored; neither can it be definitely proved. The patient had traveled extensively at home and abroad and in former years had sojourned for long periods in areas where filariasis was endemic, such as Charleston and Camden, South Carolina, and Cairo, Egypt. However, repeated examinations after the patient entered the clinic, of concentrated specimens of venous blood, failed to disclose the presence of filaria. Their absence would not exclude parasitic origin of the condition because they could cause lymphatic blockage by their dead bodies or by inflammatory fibrosis of the lymphatic vessels. Cookson and Pullar maintained that "if the patient has been at any time resident in a district in which filariasis is endemic, the chyluria may be assumed to be filarial unless convincing evidence of another etiologic factor is forthcoming." Another feature of clinical interest is the fact that the urine was milky only when first voided in the morning. This feature also was characteristic of one of the cases reported by Allen. Apparently the horizontal position favors retrograde lymphatic flow to the renal pelvis. The patient also noticed that rich, fatty meals tended to aggravate or precipitate the chyluria. Such meals possibly would be sufficient to cause a fresh discharge of chyle by increasing the flow of lymph in the vessels of the mesentery. The chylous urine seems to be the only symptom in the majority of the cases reported and this feature was exemplified in this case. Colic or discomfort, the result of coagulation of the urine before it is voided, sometimes occurs but it was not observed in the case here reported. In the interval of one month between the first and second examinations, the patient complained of some loss of weight and energy but this was attributed to a state of anxiety rather than to the loss of fat. Authorities are agreed that loss of fat which does not exceed 400 calories daily is negligible and does not account for the malnutrition and weakness of some of these patients.

In the presence of a milky urine one must exclude such possibilities as pyuria from any cause, phosphaturia, lipuria, and artificial or purposeful additions to the urine. The most elementary chemical and microscopic examinations should suffice to make a satisfactory identification of the causative substance from the laboratory standpoint. The obvious absence of those serious conditions which usually give rise to lipuria (advanced diabetes mellitus, tuberculosis, pancreatic disease, fracture of the bone, fat embolism and so forth), in the presence of fat in a molecular form, and other laboratory criteria, fairly definitely exclude lipuria. Of course it was felt that lipuria should be excluded because the patient tended to be a gourmet. Schöndorff has observed increased amounts of urinary fat after hearty eating of fatty food and after the use of fat-containing medicaments. Moreover, according to the secretory hypothesis of the genesis of chyluria, fat exists in the blood in excess and is passed by the renal epithelium. The first of these two possibilities was dismissed because chyluria occurred in the absence of dietary indiscretions and disappeared after treatment in spite of the patient's eating rich meals. The secretory hypothesis, in contrast to the mechanical one, does not rest on any secure foundation and now has few supporters. Moreover, the recent investigations of Elkan, on blood fat in cases of nonparasitic chyluria, seem definitely to nullify the secretory hypothesis.

ORGANIZATION OF THE ST. LOUIS COUNTY MEDICAL SOCIETY

By RICHARD BARDON, M.D.

IN a preceding account of the medical history of Northern Minnesota, an introduction explained the historical background of the early practitioners who were fur traders and explorers as well as doctors. This period ended with Dr. Borup, who eventually located in St. Paul in 1848.

The period from 1854 to 1886 is of vital importance, not only to Duluth but to St. Louis County as well. Up to 1854 Northern Minnesota was Indian country. In that year a treaty was negotiated with the Chippewas at La Pointe, Wisconsin, and as a result Northeastern Minnesota was open to settlement by the whites. No settlement within the present confines of Duluth was made until about 1855 or 1856, and that was very scattered. The settlement in Oneota (now West Duluth) and the present site of Duluth hardly got under way when the depression of 1857 came along, and, with the Civil War impending, settlement was entirely given up for the time being. During the Civil War and up until 1869, there was no doctor permanently located in what is now Duluth or St. Louis County. Previous to this a few pioneers who lived in the present Duluth were attended by the doctors from Superior, who, during the same period, were not very numerous. It may be of interest here to state that the chairman of the first board of county commissioners was Dr. W. W. Mayo, who was the medical officer with the Territorial Survey which laid out the northern counties of the state. There were few inhabitants in this territory. At Rice's Point, where Duluth now stands, there was one cabin, but the trapper who lived there was away, and Dr. Mayo was made temporary chairman of the board of county commissioners, an office which he held for about six weeks, until someone who lived in the county could be found to take his place. The records of the county auditor's office do not throw any light on this early appointment, but inasmuch as the office was temporary, doubtless no record was ever made. However, St. Louis County and the City of Duluth are proud to have the name of Dr. Mayo listed among their pioneers.

The earliest mention of the medical profession in the present City of Duluth is taken from the diary of the Reverend Mr. Pietezl, who spent much time among the Indians as a missionary along the south shore of Lake Superior. In 1859 he was located in the village of Oneota, and mentions that at that time one of his children was ill with a severe cold that he thought might be scarlet fever, and when the second child became much more seriously sick he called in Dr. John A. Thomson from the village of Superior, across the bay. Dr. Thomson confirmed the diagnosis. As there is no record of the child's death it may be assumed that the doctor's ministrations were successful. Dr. Thomson located in Superior in the fall of 1859, and on November 13, 1860, married Helen Rowena Abbott, daughter of Dwight and Jane Abbott, at Oneota. Shortly afterward Dr. Thomson moved to Hastings, Minnesota, and in a list of physicians

and surgeons in Merwin's Business Directory of Minnesota for 1869-1870 his address was given as "Ramsey Street, Hastings, Minnesota." Dr. Thomson died in Philadelphia on March 19, 1869, while on a visit to his father.

Dr. Thomson, born July 11, 1830, at Wilmington, Delaware, was descended of Colonial stock. His ancestors were prominently identified in civil and military capacities during the American Revolution, and received many honors for this participation. His father, Dr. James William Thomson, was a Virginian, related to many prominent Virginia families, including the Washington, Lewis, Warner, and Throckmorton families. Dr. Thomson was a man of considerable education and refinement. He graduated from Jefferson Medical College in 1851. Thereafter he did post-graduate study in Vienna, and traveled extensively abroad in Italy and Palestine.

It will be seen, then, that during the period of 1855 to 1869, Duluth had no resident physicians, and whenever necessary the doctors came from Superior. It was during this period that the pioneers had to make use of the remedies that were at hand. There are the usual stories of the midwives, the "bone setters," and the various people who had a natural bent for treating sickness. There is also the story concerning the occasional Indian who, with "tea" made from various herbs, could cure dropsy and other allied conditions. Stories are told of the treatment of gangrene by amputation and searing the stumps with red-hot frying pans! True, the people were hardy and vigorous, and possibly needed little medical attention.

Probably the first physician to locate permanently in Duluth was Dr. Edward Erastus Collins, who arrived in May, 1869. Dr. Collins was born July 26, 1833. He attended public schools in New York state, and the Brookfield Academy in New York City. After graduating from the medical college of New York in 1857, he practiced medicine in that state for a number of years, and was a contract surgeon in Washington, D. C., during the Civil War. In the winter of 1868-1869 he attended a series of lectures at the Chicago Medical College, after which he moved to Duluth. Dr. Collins practiced here until 1874, when he removed to Minneapolis, where he remained for four years. He next moved to Stoughton, Wisconsin, but returned to Duluth in 1881, where he lived until his death in 1912. Dr. Collins was a charter-member of the county medical society. Later he also engaged in the real estate business. He is best remembered as the kindly pioneer type of physician.

About the same time there were other doctors who located in Duluth, but how long they remained is unknown. In the *Duluth-Minnesotian* there appear the business cards of professional men recently located in the city. On May 19, 1869, is the name of "Guy M. Daly, Physician and Surgeon"; for June 19, 1869, "D. G. Saivy, Physician and Surgeon"; and on July 3, 1869, "T. R. Potts, Physician and Surgeon." Very little is known about these men, except that Dr. Daly practiced in Superior before coming to Duluth. Dr. Potts was graduated from the University of Pennsylvania in 1831, and was a relative of H. H. Sibley and Franklin Steele, who were well known in early Minnesota affairs. Dr. Samuel Carson McCormick arrived in Duluth in April, 1870. The reason for this sudden increase in the medical profession was the advent of the railroad connecting St. Paul and Duluth. With the completion of the railroad in 1870 Duluth began to grow. Dr. McCormick was born in Union County, Pennsylvania, September 8, 1837. He graduated from Jefferson Medical College at the outbreak of the Civil War, and immediately joined the Union forces as an army surgeon. He served with distinction throughout the war. His desire for ad-

venture still unsatisfied, he went West as a surgeon on the Union Pacific Survey, where he met the famous characters of the Wild West. Subsequently he located in Duluth. Dr. McCormick was married in 1871 to Miss Louise Smith of Superior. Her father, Dr. Vespasian Smith, had been a resident of Superior since 1857. The name of Dr. McCormick figures very prominently in the early annals of medical history in Duluth and St. Louis County. A news item for November, 1872, is interesting: "Dr. S. C. McCormick has just received a fine horse from St. Paul. Dr. Collins' purchase of a fine buggy horse seems to be contagious." A previous item stated that Dr. E. E. Collins "exhibits a fine horse, which receives the encomiums of all judges of horseflesh" In 1872 a further notice states: "Dr. McCormick has removed his office from the Bloomer Block on the Foster Lot to the building opposite—the new Hayes Brick Block, upstairs next in the rear of Col. Gow's Northern Pacific Office. The doctor has a beautiful room and his patients will no doubt want to be sick on purpose to have a prescription written from such a pleasant locality."

During the period from 1870 to 1873 Duluth increased in population, and other doctors located there, among whom were Dr. O. B. Bird, a homeopath, a Dr. Hanley and the Doctors Tanner, who came in 1871 but moved to Hudson, Wisconsin, in 1873. Their professional announcement read:

H. S. TANNER, M.D. MRS. M. J. TANNER, M.D.

Eclectic and Homeopathic Physicians offer their professional services to the citizens of Duluth and vicinity. The diseases of women and children made a specialty. Office and residence First Ave. West opp. Clark House.

Office hours from 10 to 12 A. M. and 1-3 P. M.

Carefully prepared Homeopathic medicines for family use kept for sale at our offices.

Later, Dr. Tanner achieved considerable publicity on account of his lengthy fasts. In January, 1881, the following note appeared: "Dr. H. S. Tanner began his 40 day fast yesterday at the Clarendon Hotel."

Dr. S. S. Walbank moved from Superior in 1871, and made his home in Duluth until his death in 1890. A newspaper clipping for May 4, 1890, reports his death:

"After a three weeks' illness, Dr. S. S. Walbank, one of the oldest and best known citizens of Duluth, passed into the great beyond. His death occurred yesterday afternoon, caused by pneumonia.

"Dr. Walbank was born April 30, 1823, at Morton Homestead, Devonshire, England. His medical education was received at Toronto University in 1848. He came to Superior in 1869, and cast his lot with Duluthians three years afterwards, and has since remained here. Dr. Walbank has since been identified with many of the leading projects for the upbuilding of the city. Himself and Dr. S. C. McCormick were, for a long time, the only medical practitioners in Duluth. His sterling worth and integrity as a business man, his uniform kindness and courtesy to all, has endeared him to all who knew him."

Dr. Vespasian Smith, who had lived in Superior since 1857, moved to Duluth in 1871 or shortly afterward. Dr. Smith figures frequently in the early civic and medical development of Duluth, and was mayor for two terms (1873 and 1874).

In the "History of St. Louis County," page 472, there is an episode worth recording:

"Dr. Vespasian Smith was a staunch, sterling old character, that builded well with his great common sense, while enlivening his fellows, as they went, with his kindly humor. He became mayor of the city in April, 1873, and he got 226 votes, but one being cast against him. When his term was out he was again elected, but he was not so fortunate this time, for there were three votes cast against him. He used to say that the only vote against him the first time was his own, but that during his second term he made two enemies, so there were three votes against him on his second election."

Dr. Smith was born in Mount Vernon, Ohio, October 23, 1818, of old Virginia stock. He first showed an inclination to become a trader among the Indians, but after only a year took up the study of medicine under a preceptor, later attending the medical department of Western Reserve University, from which he was graduated in 1851. After practicing for several years in smaller Ohio towns he came to Superior in 1857. Evidently he was quite a politician, for he was soon appointed physician to the Chippewas at the Bayfield agency. Thereafter he held some political appointment continuously, from his first under Buchanan until the time of his death, with the exception of the Cleveland administration. He was a member of the Minnesota State Board of Health for twenty years. Inasmuch as Dr. Smith figures frequently later on in this narrative, his activities will not be further enumerated at this point. He died in 1897. His son, Frank Smith, owned and operated one of the earliest drug stores in Duluth.

One of the early medical pioneers of Duluth, who was not actively engaged in medical practice, so far as could be ascertained, was Dr. Thomas Foster. He came to Duluth in 1868 from St. Paul. Dr. Foster published the first newspaper in Duluth, the *Duluth-Minnesotian,* which appeared on April 23, 1869. Dr. Foster was a unique character, and a biographical sketch of his life is interesting, not because of his work as a physician but because of his political activities. He was born May 18, 1818, in a southern suburb of Philadelphia. He studied medicine for a time under the preceptorship of Dr. Ord of Lewistown, Pennsylvania, but gave it up to enter the newspaper business and engage in politics. While in Uniontown, Pennsylvania, he again took up the study of medicine, and probably practiced for a short time, when he returned to the newspaper business and politics. In 1848 he became secretary of the Whig State Committee of Pennsylvania, of which Alexander Ramsey was chairman. Dr. Foster accompanied Ramsey to Minnesota as his secretary when Ramsey was appointed territorial governor. When Ramsey became state governor Dr. Foster was again appointed his secretary. For a time previous to 1860 he published the *Daily Minnesotian* in St. Paul. He served in the commissary department of the army during the Civil War, with the rank of captain. In 1867 Dr. Foster was chairman of the Republican state committee of Minnesota. The same year he edited the first daily paper in Minneapolis, *The Chronicle.* In 1868 he arrived in Duluth. Just how long he remained there is difficult to state, as the paper soon passed out of his control. He eventually obtained a clerkship in the postoffice department in Washington, and in 1902 moved to San Francisco, where he died shortly thereafter.

During the early seventies epidemics of scarlet fever were frequent. In a column of the *Daily Minnesotian,* under the caption "Local Rip-Raps," was the statement pertaining to "that terrible epidemic to children of scarlet fever, which still continues to linger in our city, and many of the little ones are lying under its dreadful scourge." In subsequent issues it appears that the epidemic continued to afflict the city until the spring of 1876, with consequent mortality to many children. During the winter, records show that schools were closed in an effort

to control the spread of infection. In 1876 it was reported that Dr. S. C. McCormick was health officer and Dr. Vespasian Smith was appointed "a private member of the board of health." About this time Drs. J. L. Graham and C. H. Graff arrived in Duluth.

The coming of the railroad and the cutting of the canal in the early seventies was a great stimulation to the struggling village. In the panic of 1873 Jay Cooke, who financed the Northern Pacific, failed and the city was at a standstill. However, with the discovery of iron ore on the Vermillion Range in the early eighties, and with the development of the lumbering industry, the city began to grow rapidly. Throughout this period the medical profession was unorganized. Hospital facilities were lacking until the establishment of St. Luke's in 1882. There is mention of a "temporary hospital" in 1871, but evidently it did not grow into a permanent institution. St. Mary's Hospital was not founded until 1888.

The newspaper reported for February 2, 1882, that "Dr. Bowman had a telephone put in his office in the Hayes Block yesterday."

The Board of Health was created in 1884, and "the streets and alleys of the Village were thoroughly inspected and several old timers were deprived of their almost immemorial privileges of keeping pig-pens underneath their neighbors' windows and of maintaining other nuisances to the neighborhood, much to their indignation."

This was Duluth at the time the St. Louis County Medical Society was proposed.

The exact date of the formation of the St. Louis County Medical Society was unknown until December, 1936, when on checking through some of the old newspaper files it was ascertained that the year of the founding was 1886 instead of 1887 as recalled by Dr. McComb. The early records of the Society have been lost or misplaced, and there are various theories as to just what happened to them. There is the story that they were burned when fire destroyed an office building. However, this is somewhat questionable and no doubt they were thrown out, as so many historical records have been in the past. In the newspaper files for June 26, 1886, this item appears:

A CALL

To the Physicians of St. Louis County

Notice is hereby given that a meeting will be held for the organization of a County Medical Society of St. Louis County, Thursday next, July 16, 1886, at 8 p. m., at Dr. McComb's office.

This is interesting, because Dr. McComb stated that the first meeting was in the office of Dr. S. C. McComb in the Norris-McDougall Block, which at that time was a popular building for doctors. On the following day there was a notice in the paper reporting that

"The St. Louis County Medical Society met in council on Thursday night, July 16, to form a county association for mutual protection and improvement, and after the preliminary business a committee was appointed to draft a table of fees and report thereon at the next meeting. The following well-known medical men were elected as officers for the ensuing year:

President	Dr. V. Smith
First Vice President	Dr. A. F. Ritchie
Second Vice President	Dr. S. C. McCormick
Secretary	Dr. Stocker
Treasurer	Dr. McComb
Censors	Drs. Sherwin, Magie and Speier

"The elections being decided, the meeting adjourned, to meet on the second Thursday in August, and will meet on the second Thursday in each and every month."

There is very little known about the early meetings of the society except that Dr. McComb states that the meetings were rather informal and discussions were always in order. Dr. Stocker apparently was a very careful secretary, and it is certainly a calamity that his records have not been preserved so that we might have first hand information as to just what went on. Those who saw the early minutes always recall the perfection of the handwriting and the great detail and exactness of Dr. Stocker's reports.

During the year 1886, in coöperation with the Duluth Chamber of Commerce or its predecessor, an attempt was made to get the State Medical Society to meet in Duluth the following year. This was successful. Dr. McComb recalled that the meeting was successful in many ways, inasmuch as he was elected president of the state society and was introduced to the members by the late Dr. W. W. Mayo. At that time Dr. McComb was only twenty-nine years of age, and had been a resident of Duluth since 1883. Subsequently he had been president of the county society on two occasions the second time during a state meeting there, but he was unable to supply the exact dates.

In a newspaper file for September 10, 1887, there is a note on a meeting of the St. Louis County Medical Society, and it is of sufficient interest to have it reproduced:

"A meeting of the St. Louis Medical Society was held in the office of Dr. Magie on Thursday evening, at which the following members of the profession were present: Drs. Ritchie, McComb, McCormick, McAuliffe, Judd, Speier, Sherwin, Davis, Magie, Stocker and Dr. Specht of West Superior. Pres. Ritchie occupied the chair and Secretary Stocker recorded the minutes. The first paper on 'The Ophthalmoscope as One of the Main Factors in Diagnosing Obscure Diseases,' was read by Dr. McAuliffe. A discussion followed, in which various members gave their experiences on the subject. An oral debate opened by Dr. Stocker was quite interesting. It was in regard to 'The Treatment and Causes of Summer Complaint and Intestinal Catarrh.' Another discussion was participated in by several regarding 'Contraction of the Pupil and Affection of the Eyesight Resulting from Injuries to the Spine.' Dr. Stocker led this discussion also."

The calibre of this program is remarkable, and is an indication of the progressiveness of the young society.

There is another notation in the newspaper for June 16, 1887, which stated:

"The Medical Association will commence tomorrow morning at 10 o'clock. Dr. S. C. McCormick, Chairman of the committee of arrangements, requests 'The News' to say that, owing to the unavoidable absence of Dr. H. H. Kimball, Pres. of Minnesota State Medical Society, Dr. W. L. Beebe of St. Cloud, 1st Vice Pres., will be the acting President. The Society will be divided into two sections. Dr. R. D. Barber of Washington, 2nd Vice Pres., will preside over the first section and Dr. A. Holmes of Oronocco, 3rd Vice Pres., will preside over the 2nd section."

It is of interest to note that at the very first meeting of the county society there was some question regarding a standardization of the medical fees. Dr. McComb states that it was customary at that time to get $1.50 for a day call and $1.00 for an office call, or, as he calls it, "a prescription." After considerable debate the society decided to raise the day calls from $1.50 to $2.00. This, according to some of the members, was not entirely sufficient, but it eventually became the standard fee for a good many years.

The first annual banquet of the society was held at the Spalding Hotel in 1895, and it was customary during those years not only to have a sumptuous

repast but plenty of liquid refreshments as well! In 1895 the state society again met in Duluth and the local committee in charge of arrangements was Dr. W. H. Magie, chairman, Dr. C. F. McComb, Dr. C. A. Stewart, Dr. S. C. McCormick. At that time Dr. Justus Ohage of St. Paul was president, and the meeting was on June 19.

The decade from 1880 to 1890 saw many changes in the medical profession, and Duluth as well. The hospitals were being developed, the Board of Health set up, and the medical society organized. Sanitary conditions in the city, however, continued to be a source of dissatisfaction, with typhoid an ever present menace.

The "Mortuary Report" for September, 1888, furnishes an interesting sidelight on vital statistics of the period:

"Total Number of deaths reported.....48

"Cause 1 Railroad accident
1 Drowning
1 Capillary Bronchitis
6 Cholera Infantum
1 Convulsions
2 Diarrhea
2 Dysentery
1 Enteritis
1 Entero-colitis
2 Heart disease
1 Pulmonary hemorrhage
1 Indigestion
1 Marasmus
1 Chronic nephritis
2 Phthisis pneumonia
1 Traumatic peritonitis
17 Typhoid Fever
7 (Not reported)

Dr. Sherwin,
Health Officer."

The population of the county was increasing rapidly, and many physicians whose names are now familiar appeared in the news of the times.

(To be continued in April, 1938, issue)

Social Scientists and Medical Care

MICHAEL DAVIS, Ph.D.,* of New York, has recently circularized the profession quite generally and has codified the "Social Scientists' " viewpoint in regard to "organized medical care." These two final sentences in his summary deserve impartial scrutiny: "Medical service must be judged from the point of view of the people who receive and pay for it, as well as from the standpoint of the physicians and institutions that furnish it. The participation of medical and social scientists is therefore needed in appraisal as well as in planning, and the rate and smoothness of progress will depend largely upon ungrudging coöperation between physicians and the public."

It would appear that the *science* in *social* achievement is on a par with that which obtains in Medicine, if we are to accept the author's thesis. It is not for us to acclaim that we represent science in all our medical achievement. Much of what we individually accomplish may well be grouped under priestly or even less dignified effort to appease the unrest inherent in man's conflict with his consciousness.

We may go a considerable distance with the social propagandists and lend them recognition, and even example (should they seek to follow it), in seeking to utilize science in their economic and humanitarian efforts, but at this time it is only reasonable to ask them how far they have gotten. Some ten years ago I overheard in Switzerland a distinguished Continental economist remark that social economics and political government were at the stage of scientific attainment that Astronomy held when Copernicus announced his theory of the universe! It is said that one of the major causes for wreckage in the recent German Republic was the attempt to acccomplish social and economic security by edicts. Many of these dealt with matters of health, unemployment, old age, and the usual penalties of circumstance. Idealistic efforts no doubt added to the immediate popularity of a socialistic regime. It all looked very promising on paper. Within a comparatively short time, however, these measures lent disaster, not only to organized medicine but to the economic stability of a country tested far beyond its capacity. Reform had outrun itself.

Missionaries have long resorted to approaching the heathen's soul via the route of caring for his bodily ailments. There is a subtle compliment to our profession in that observation. These social and economic reformers would en-

*Facts and issues regarding public medical care, New England Jour. Med., 218:143-47, (Jan. 27) 1938.

joy teaming up with us in order to make more palatable a re-deal of the cards in a game in which they establish most of the rules and base all of them upon experiment. "The public medical care" is indeed a problem. However, the success in the Twin Cities, in Minnesota, of the hospital insurance plan for employed groups, would indicate that the hospitals at least are far from ready to turn over their management to governmental bureaucratic guidance. Movements of this order point the way for tying up our scientific heritage with such portions of social advancement as are workable and judicious. We have come a long way in a muddling world; and for the most part independent of Government subsidies or entanglements. Whatever socialization we absorb should be like the dosage of our drugs—"quantum sufficit," and no more.

E. L. T.

Marihuana

THE rumors that have been growing more insistent the past few years about the increasing use of marihuana in our country, evidently have some basis in fact. Marihuana, also spelled marijuana, is the term used for that portion of the plant Cannabis Sativa, a species of Indian hemp, containing the drug. Although all but one of the states have had laws governing the raising and use of Indian hemp, last summer the Federal government took cognizance of the growing evil and passed the Marihuana Tax Act. An article* written from information furnished by H. J. Anslinger, United States Commissioner of Narcotics, and abstracted in the *Reader's Digest* for February, emphasizes, perhaps with overemphasis, the enormity of the growing evil.

Indian hemp grows wild in all parts of the United States and is cultivated in the east. Its stalk has commercial value, while Cannabis Indica preparations are obtained from the flowering tops of the plant and its resin.

The drug may be taken by mouth or can be incorporated in a cigarette, which method is said to have originated in Mexico and to have spread into this country rapidly the past two or three years. These cigarettes, known as reefers, are being peddled particularly to the youth of the country.

The drug and its psychic effects are not new. Homer described how it made the victims forget their families and turned them into swine. It is the hashish of Oriental reputation. While its action is unpredictable it usually causes hilarity at first, loss of judgment and eventually somnolence. During stimulation the mind acts so nimbly that the passing of time seems slowed. Most atrocious crimes have been committed following the use of the drug. Our word "assassin" is derived from this Arabic word "hashish."

The Federal Marihuana Tax Act requires registration of all those who grow or handle the plant. The mature stalks of the plant are excepted. In an effort to control marihuana, physicians wishing to prescribe Cannabis Indica preparations are required to pay a special tax of one dollar yearly and keep a record of their prescriptions. Needless to say, few physicians will wish to prescribe the drug, for its narcotic effect for which it is mentioned in pharmacopœias is far surpassed by many safer drugs.

The widespread wild growth of Indian hemp will make its control difficult. The very fact that it is so available, however, has prevented marihuana from coming under the control of gangster syndicates. Publicity and emphatic warning of the grave danger incident to the use of the weed will, it is to be hoped, nip in the bud the spread of the traffic in the weed.

*Anslinger, H. J., with Cooper, Courtney Ryley: Marijuana—Assassin of youth. American Magazine, July, 1937.

Mea Culpa and Its Author

EVER since the days of Tobias Smollett (1721-1771) and Oliver Goldsmith (1728-1774), both of whom were rank failures as physicians, the pursuit of literature as an auxiliary to the profession for which they were originally trained has appealed to medical men. Many who were wholly unknown in medicine have become famous as writers. Some, like Oliver Wendell Holmes and S. Weir Mitchell, made substantial contributions both to medical and general literature and were eminent in both professional fields, but that is unusual. Gen-

erally speaking, when a man has made his mark as a writer he has abandoned medicine; there have been very few exceptions to this rule and the two last named were not among them, in their later years.

Contemporary writers who began as physicians, like Deeping, Maugham and Cronin in England, Léon Daudet and Georges Duhamel in France and others in this country, have been mentioned in some detail in these columns by the present writer (MINNESOTA MEDICINE, December, 1935) and further reference to them at this time is unnecessary. But another French physician-author was referred to casually and it is to his later efforts and his own peculiar life and personality that brief consideration is now being given.

Louis-Ferdinand Destouches was born in 1894 in Asnières, a small pleasure-resort suburb on the left bank of the Seine, three miles north of Paris. After a boyhood of poverty and misery he found himself, at twenty, sent to the front in the first stresses of the World War, out of which he came with a brain injury, a definite psychosis and functional cerebral disturbances which have never disappeared. He studied medicine, with intermissions for economic reasons in which he went first to the French colonies in Africa, later finishing his studies and writing the doctorate thesis which gained him his degree in 1924. Then he went to the Ford factories and filled a medical post at Dearborn, afterwards going to Africa under the auspices of the Rockfeller Institute to investigate tropical sleeping sickness.

Back in Paris, finally, he secured an outpatient connection with a hospital in the Montmartre district, picked up some practice among the poor and then began writing. His first effort was a laborious affair, immensely bulky and so fantastic and radical that he refused to allow it to be published as his own. Our comment on it at the time was that "in form it resembles closely a very prolonged example of what our psychiatric friends would call a 'flight of ideas.'" Destouches said that its publication over his own name would indicate that he was not merely exposing himself to mockery but also making the whole literary profession appear foolish. This was his *Journey to the End of the Night* and he ultimately allowed it to appear, in 1932, as the work of Louis-Ferdinand Céline, the last being the name of his mother, a pen name which he continues to use. This book aroused a perfect tempest of vituperative criticism and also stimulated the vigorous support of an influential band of well known literary critics. Widely translated, it made him world famous.

His next effort, published in 1936, not yet available in translation, is entitled *Mort à Credit* (Death in Deferred Payments, or on the Instalment Plan, as you please) and is said to be another bulky volume, "even more impressive than the first, more profound, more daring, more shocking, and more penetrating in its exploration of life."

But the book which has excited the present remarks is a small volume of 175 pages, recently published with the title of *Mea Culpa* and *The Life and Work of Semmelweis*, translated by Robert Allerton Parker, of New York. Only the first thirty-six pages are devoted to *Mea Culpa*. Why he should blame himself is not easy to understand. Destouches went to Russia in 1936, an avowed Communist, to study conditions at first hand and came back bitterly disillusioned. *Mea Culpa* is the story, terrifically told. It gives one the impression that the psychotic author has a guilt complex over the situation in Russia. The remaining five-sixths of the book is a translation of the author's doctorate address written in 1924, a dramatic story of the tragic efforts of Philip Ignaz Semmelweis to secure recognition of the contagiousness of puerperal fever, unsuccessfully carried on from 1846 to 1865, when Semmelweis died in an institution for the insane, the victim of a self-produced infection.

Destouches, or perhaps we should call him Céline since he has adopted that name, writes in the patois of the underworld of Paris, the argot of the criminal classes which is said to have been old even in the days of François Villon and which corresponds in a measure to our newer "crook lingo." This has made the task of the translator, Mr. Parker, exceedingly difficult and he has had the additional handicap of the layman in dealing with the occasional medical terms which have crept in. But on the whole he has done well, acknowledging freely his indebtedness to a qualified French collaborator.

President's Message

AT THE Northwest Regional Conference held recently in Chicago, the general theme for discussion was: "Medical Care for All the People." The discussions were led by officers of the national, state and county societies. The consensus of opinion seemed quite well crystallized about the fact that the county must be the responsible unit for the care of the sick. Climatic conditions, the variable types of citizenship, economic conditions, and many other factors make it impossible to establish a plan for the medical care of all the people which would be applicable to all parts of the country. To a lesser degree the same holds true in attempting to formulate a state-wide plan. Of the eighty-seven counties in Minnesota, perhaps the same plan may be applicable to about one-third this number. Many are able to take care of their own indigent and other medical problems. Some are sparsely settled and financially low. It is necessary for the state to come to their rescue. To determine which counties should have outside assistance and just how much is no small task. Our State Board of Control and State Relief Department, in conjunction with the Local County Welfare Boards and local committees of the County Medical Societies, are doing excellent work in formulating workable plans for these various needy counties. To coördinate these various agencies a central authority is necessary. Our State Association has done well in this capacity. At our Regional Conference, seventeen states were represented. So far as I could ascertain, no state represented at this conference had a better set-up for the care of the sick than has Minnesota, and few have as good.

Our State Board of Health, Public Health Association and Medical Society have the co-operation of the state and federal relief groups in every move to improve the care of the needy sick. We all acknowledge the need for improvement and all are striving for such improvement. In former years duplication of effort was confusing and wasteful. Today this seems to be eliminated to a high degree.

While all our various state and county organizations are doing their best to work in unison and care for the sick to their best ability, we hope we all may learn and improve our methods from our contact with those from other states and counties. A study of their various plans and experiences should help us in our attempts to formulate workable plans throughout the state.

To me one of the most attractive parts of the program put on in Chicago was the outline of the Health Program in the state of Indiana. Such a program means much work, but I believe it is worthwhile in making the public medically conscious. I hope some day we may have such a program in Minnesota.

J. M. HAYES, M.D.

New Call to Action

For several years the American Medical Association has been urging county and state medical associations to experiment with new plans for the care of the indigent and low income groups.

The result has been a considerable amount of healthy activity in many parts of the United States.

It was not the type of activity that catches the public eye or fires the public imagination, however, and it has clearly become desirable, now, for organized medicine to take action on a large scale. Furthermore, a nation-wide, organized effort on the part of organized medicine promises to be more effective, now, than ever before.

Thank you, Mr. Governor!

On January 28, 1938, the Honorable Elmer A. Benson, Governor of the State of Minnesota, announced the appointment of Dr. John E. Indihar of Chisholm, Minnesota, to the Minnesota State Board of Health for a three-year term. Dr. Indihar is a highly respected member of the dental profession practicing at Chisholm. He was born at Sparta Junction, Minnesota, and is thirty-eight years of age. Following graduation from high school at Gilbert, he received his degree in dentistry at Marquette University in 1923. Dr. Indihar is a member of the Duluth District Dental Society, the Minnesota State Dental Association and the American Dental Association. He succeeds a chiropractor on the Board of Health and we are sure that he will make a most welcome addition to the Board. Those who know him will attest to his energy, modesty and sincerity.

Indeed, Governor Benson, a splendid change and one entirely consistent with the principles that should guide the State Board of Health. At the same time Governor Benson announced the reappointment of Dr. William A. Brand of Redwood Falls and Dr. Nels G. Mortensen of Saint Paul to the Board of Health. For the entire medical profession we say, Thank You!

The action taken recently by the Board of Trustees calls first for a thorough study of the medical needs of their own communities on the part of all state and county medical societies. A comprehensive outline of the two phases which such a study must cover—the demand for services on the one hand, and the supply available—has already been sent to all State societies.

Time is Ripe

The time is ripe for a new study of medical services in the United States and it is right and proper that this study should be under medical auspices.

Several years have passed since the Committee on Costs of Medical Care made its report and times have greatly changed. The studies made recently by the United States Public Health Service on the amount of chronic illness in this country have filled in some parts of the current health picture; but new and authoritative data are needed on the actual condition of medical services and the need for extended care.

The next step will be, of course, to work out some practical plan in every community where it may be needed, to meet that individual community need.

Acts of Congress and heavy appropriations are not necessary for practical action of this sort. For medical men this is the time and opportunity to show that medicine can and will make any needed adjustments that it may uncover without outside aid.

Council Will Act

The outline for the study, prepared by Dr. R. G. Leland, director of the Bureau of Medical Economics, will be presented shortly to the Council for decision as to Minnesota's participation in this nation-wide study.

Northwest Conference

The Northwest Regional Conference originated in Minnesota in 1927 when Dr. W. F. Braasch was president of the Minnesota State Medical Association and it was held in Saint Paul under the auspices of the Minnesota Association for many years.

At the meeting held February 12 in Chicago, President J. M. Hayes, Dr. Braasch and Mr. R. R. Rosell, executive secretary, represented the Association.

Following are some interesting highlights on public welfare work carried on by a few of the seventeen state societies participating. They furnish evidence of a fact that was strikingly evident to those who were present at the 1938 meeting: Organized Medicine has moved rapidly in the last few years along the road to efficient handling of relief and welfare problems that involve care of the sick in their own communities.

Preventing Disease

Indiana.—A general public health education program is carried on by all the county societies in the state, according to a definite schedule that changes monthly. For example, February was devoted to syphilis education; March is to be devoted to the pneumonia program; April to cancer. News stories sent out from the state

office follow the program throughout the state. Special talks, health exhibits, demonstrations, mark each campaign.

Roving Committee

Wisconsin.—As a result of last year's long fight in the legislature to defeat the Beimiller bills (for sickness insurance, state subsidies, et cetera) the Wisconsin State Medical Society is now engaged in what is perhaps the most thoroughgoing study ever made in any state as to medical care, adequacy of facilities, costs. A roving committee, so-called, goes into each community, meets with representative groups including representatives of all leading service organizations, Rotary and Kiwanis clubs, churches, carefully studies the local situation, makes notes of findings. A permanent committee is left behind which will study the problem further and report to the state society. The committee is still assembling information and no reports have been issued to date. It will be remembered, in this connection, that the Wisconsin Society is also sending its executive secretary, Mr. George Crownhart, to Europe this spring to make a first-hand study of sickness insurance systems in European countries.

Rehabilitating Sick Men

West Virginia.—The West Virginia State Medical Society is carrying on a significant demonstration of the value in money to the state of the medical rehabilitation of otherwise unemployable relief clients. The society started with a trial of appropriation of $1,000 to be used for the rehabilitation of ten men. This cost was determined on the basis of a survey by which they also showed to the state that it was costing an average of $224 to maintain the same unemployables on relief. At the end of the first year the medical men returned each of the ten men to regular jobs. The accomplishment so impressed relief authorities of the state that a large appropriation is now set aside each year for the rehabilitation of unemployables. It is estimated that the state saved $169,120 during the last year.

Cutting Red Tape

Oakland County, Michigan.—The Oakland County Medical Society has developed a working alliance with county relief authorities whereby any relief client may apply at any time to the doctor of his choice, without any preliminary authorization whatever, for needed medical service. The procedure is this: the relief client calls the doctor or visits his office; the doctor gives him whatever care or advice may be immediately needed and signs the patient's own identification card; *subsequently,* within seven days from the date of the first visit, the doctor sends to the relief office a statement on a simple form as to the call, name and identification of the patient, diagnosis, need, if any, for further service. Further care is given as needed on the basis of a fee schedule determined by an advisory committee of the medical society and the medical director of the relief administration. Discipline of physicians who might chisel is the responsibility of the advisory committee. The plan has worked, with additions and notable developments, in Oakland County (population about 200,000, largest city, Pontiac) since 1934.

County Society Clinic

Sedgwick County, Wichita, Kansas.—The Sedgwick County Medical Society has formed a clinic for the handling of medical care for relief patients. A lump sum of $500 is paid to the society for the service and all relief patients apply to the clinic for medical aid. The society also operates a credit bureau and collection agency for its members. Low income patients who are unable to pay regular fees are referred to the bureau, their needs and bills budgeted and the care administered at costs within their ability to pay.

Government Medicine

Statements frequently have been made to the effect that the government institutes postgraduate training for members of the panel in the countries where compulsory sickness insurance is in force.

In a recent issue of the *British Medical Journal* it was announced that arrangements had been made to give a course of postgraduate instruction to some forty-five members of the panel over a period of two weeks. One cannot help but compare this with the opportunities for graduate instruction available to members of the medical profession in this country,—and this under the spur of individual initiative.

There is a great variety of opportunities here. For instance, in Michigan practically all the doctors go to school at least two months out of a year. Instead of giving up their entire practice, the graduate lectures and demonstrations are brought to various parts of the state so that the physicians will have to sacrifice but two or three hours a day two or three times a week. So-called refresher courses are given by many state universities in regular centers over a period of a week or two. The annual meetings of the state, as well as national medical societies, are made centers for graduate education. There are many other agencies for graduate instruction, such as the College of Surgeons, the Inter-State Assembly, hospital clinics, beside the courses which are arranged by the various county societies in the larger medical centers. Opportunities are continually being increased so as to reach the majority of the practitioners.

Many of these activities are now being described in detail in the Economic Columns of *The Journal of the American Medical Association.*

One would hesitate to predict what might happen to these manifold opportunities if American medicine should ever be controlled by the state. There would be but little incentive to maintain the present facilities and those which might be developed undoubtedly would be restricted and stereotyped by governmental control. This is only one more of the calamities which would befall medicine if our socialistic friends had their way.

"Forewarnings"

(Monthly Editorial by the Medical Advisory Committee)

Four cases in four days, each with a potential warning to the members of our Association, were reviewed by the Medical Advisory Committee the first week in February.

1. A case of alleged unauthorized autopsy.

In no case should an autopsy be performed except by the duly constituted authority authorized by law to perform such autopsies unless written permission which has been signed by the next of kin and notarized or witnessed is in your hands.

2. A case of alleged negligence.

Never fail to examine a case thoroughly even though you do not feel it necessary. If you haven't time, make a future date or send the patient to someone else who has the time. If the patient will not do as you wish, refuse to treat him until he will. Better to lose the patient than to lose a malpractice suit.

3. A case of giving unauthorized information.

Information obtained from a patient should be kept confidential. There is no finer relationship than the patient-physician relationship. Lawyers and others are not entitled to information unless the patient signs the request. Be sure again that the request is notarized or witnessed. It may save you trouble.

4. A case where an assistant talked out of turn.

When cases are referred to associates or assistants for care, see that they are fully aware of their responsibility to you or to the surgeon who formerly treated the case. A derogatory word spoken by an unthinking or irresponsible assistant caused the last case reviewed.

If foresight is better than hindsight, then forewarning, if heeded, will save disaster in many a case. Take heed to the "mariner who watches the thin clouds and takes a reef in his sails, before the storm breaks."

Remember

Deductions for expenses incurred in attendance at medical meetings and in postgraduate study may now be made by physicians in making state income tax returns.

This new ruling made by the Minnesota Tax Commission brings the state regulations into conformity with federal income tax regulations in this matter. Physicians who have not yet made returns should remember this ruling.

"Sorry for Their Patients"

"I cannot understand why so few men attend their county and state medical society meetings. It is not because they are so busy, as the busiest doctors are always found where there is a chance to learn. After years of observation I have reached the conclusion that there are three kinds of physicians who don't attend meetings: the

person who has not the ability to plan his work so that he can have an evening for recreation at the meeting; second, the man who thinks he knows it all, has not read a new book since leaving school, and has no time for reading the journal or other publication; and third, the man who is afraid he might lose a patient should he leave his office. These three types form the fault finding group, complaining, but will not come to the meetings and put their shoulders to the wheel, clarify their visions, help remove the faults they see and become what is most needed by the society and always welcomed by its officers—a worker instead of a drone or complainer.

"Yes, the opportunity for the present-day doctor to be an up-to-date doctor is right at one's door, and I am not only sorry for those who are missing these opportunities, but for their patients."—*Pittsburgh Medical Bulletin.*

Minnesota State Board of Medical Examiners

Self-Styled Health Expert Loses in Supreme Court

Re State of Minnesota vs. Vivi Ann Mielke, also known as Vivi Ann Wyntor.

On February 4, 1938, the Supreme Court of Minnesota, in a unanimous decision, held that the above defendant, who represented herself in Minnesota as a health expert, had brought herself "squarely within the basic science law" by her conduct. The opinion of the Supreme Court, which is printed in full at the end of this article, was written by the Honorable Charles Loring, Associate Justice. The opinion is clear and concise and should go a long ways to effectively demonstrate that quackery will not be tolerated in Minnesota through any such attempted evasion of the law.

Following the decision of the Supreme Court, the defendant appeared in the District Court of Ramsey County, and entered a plea of guilty on February 14, 1938, to the amended information charging her with practicing healing without a basic science certificate. The plea of guilty was entered before the Honorable Richard A. Walsh, Judge of the District Court, who, after hearing the facts and questioning the defendant, imposed a fine of $100.00 or thirty days in the Saint Paul Workhouse. The fine was paid. The disposition of the case was recommended by the County Attorney's office of Ramsey County, and the Minnesota State Board of Medical Examiners because the defendant was also obliged to pay the expense of the appeal to the Supreme Court. Judge Walsh, in passing sentence, remarked that, in view of the Supreme Court's decision, the defendant had clearly violated the law; Judge Walsh also stated that the basic science law was enacted to protect the people against such things.

The defendant, who is twenty-five years of age, was arrested at the Lowry Hotel in Saint Paul, on April 23, 1937, following an investigation conducted by the State Board of Medical Examiners and the Saint Paul Police Department. At that time the defendant was released upon $500.00 bail, waived her preliminary hearing when arraigned in Municipal Court on April 24, and was held to the District Court, where she was arraigned on April 26. The case was continued to May 10, 1937, and reset for trial on May 18, on which date an amended information was filed setting forth the charge in considerable detail. A demurrer was interposed by the defendant and on July 12, 1937, the Honorable Richard D. O'Brien, Judge of the District Court, made an order overruling the demurrer and certified the case to the Supreme Court of Minnesota for a decision as to whether or not the amended information charged the defendant with a public offense. The information alleged that the defendant had advertised herself as an assistant and staff lecturer for one R. A. Richardson, an osteopath of Kansas City, Missouri, who holds no license to practice any form of healing in the State of Minnesota. It also charged her with giving free lectures at the Lowry Hotel in Saint Paul, following which she gave a lecture course on health matters for which she charged a fee of $5.50; that during these lectures she advertised certain products including pills, tablets and other preparations which she had for sale. These concoctions were represented as being used in the treatment of anemia, thyroid disturbances and a multitude of other conditions.

The defendant, at the time of her arrest, maintained an office in the Lyceum Building at Duluth. She also operated in Virginia, Hibbing and St. Cloud. She admitted that she had never studied medicine and that her only training for this type of work was supplied by Richardson.

The defendant was represented by George H. Lommen, State Senator from Eveleth, Minnesota, who devoted a great deal of his time and argument in a futile attempt to divert attention from the real issue by attacking the medical profession. The State was represented by the Honorable William S. Ervin, Attorney General of Minnesota; Mr. Roy C. Frank, Assistant Attorney General; Mr. M. F. Kinkead, County Attorney of Ramsey County, and his assistants, Mr. James F. Lynch and Mr. Horace R. Hansen.

No. 4 Ramsey County Loring, J.
State of Minnesota, Plaintiff,
31501 vs.
Vivi Ann Mielke, also known as
Vivi Ann Wyntor, Defendant.
Endorsed:
Filed February 4, 1938.
Russell O. Gunderson, Clerk,
Minn. Supreme Court.

SYLLABUS

An information examined and found to charge defendant with practicing healing without a certificate under the Basic Science Act. The requirements of that act are germane to the protection of the public as applied to the acts charged against the defendant.

The question certified to us is properly answered in the affirmative.

OPINION

LORING, Justice.

The trial court has certified to this court the question: "Does the amended information as filed charge a public offense under the Basic Science Act of the State of Minnesota as set out in Section 5705 of Mason's Minnesota Statutes for the year 1927?" The amended information charges the defendant with practicing healing as defined by law without a valid existing certificate of registration in the basic sciences. As amended the information charges the defendant with advertising herself as an assistant and staff lecturer for Dr. R. A. Richardson of Kansas City, and that she would give free daily lectures commencing April 13, 1937, to and including April 15 of that year; that she gave the lectures at the Lowry Hotel in Saint Paul, and during the lectures solicited women present to attend a lecture course which would follow immediately, for which a fee was charged; that a number of women attended and paid the fee, and during the lectures certain products or

concoctions were described and their uses and values discussed and certain circulars were distributed by and under the direction of the defendant, which circulars further described such products; that during the lectures it was announced that she had such products for sale, and she suggested and recommended their purchase by her hearers, who actually bought them from her at the Lowry Hotel; that from these sales she derived a commission of 55 per cent, the remainder going to Dr. Richardson, who was an osteopath holding no license to practice healing in the state of Minnesota; that one of the paragraphs in the circulars distributed by her was entitled: "How to Improve Your Health and Personal Appearance," and that it stated further:

"An anemia condition of the blood may mean either a deficiency of the blood itself or a deficiency of its red blood corpuscles.

"Recent scientific discoveries have proved the effectiveness of powdered bone marrow and spleen in the symptomatic treatment of anemia. This treatment offers greater promise of success than previous treatments, and it is endorsed by physicians.

"The effect of red bone marrow and spleen is shown in several ways. It has been found that these substances increase the formation of red blood corpuscles and their hemoglobin content. They also serve as an increased resistance to the process of hemolysis. By this process the hemoglobin or iron content of the blood is separated from the corpuscles and appears in the blood serum. Red bone marrow and spleen has a tendency to make the blood coagulate more quickly, and in this connection it has been used very effectively in the treatment of abnormally profuse menstruation."

She offered for sale tablets claimed to contain red bone marrow and spleen and labeled: "Useful in Secondary Anemia." Circulars which she distributed contained the following paragraphs:

"Women may become excessively fat or unusually thin, or have other physical disturbances. For instance, the young woman whose female organs are not functioning properly, and whose menstrual periods are irregular, practically always has a deficiency of glandular secretions. The thyroid gland as well as the ovarian glands, is practically always involved.

"The reason we feel so certain that both the thyroid and ovarian glands are concerned is because when thyroid and ovarian substances are supplied, the condition invariably improves. Not only does the patient feel better, but she is more alive and alert, and her complex, the light in her eyes, and the cheerfulness of her expression, all prove that the very thing she needed was glandular food, or female hormones."

Defendant is also charged with having sold female hormone tablets in connection with the lecture.

The Basic Science Law, Sec. 5705-1 et seq., Mason Minn. St., forbids the practice of healing without first having obtained a certificate of having passed an examination by the state board of examiners in the basic sciences. By the terms of the act, the basic sciences are defined to include the following: anatomy, physiology, pathology, bacteriology, hygiene, and chemistry insofar as the same relates to the human system or mind as generally treated in each or all of said subjects. The practice of healing is defined by the act as including any persons who shall in any manner for fee, gift, compensation or reward, or in expectation thereof, engage in the diagnosis, analysis, treatment, correction or cure of any disease, injury, defect, deformity, infirmity, ailment or affliction of human beings or who for any fee suggests, recommends or prescribes any medicine or cure thereof.

The defendant does not attack the constitutionality of the basic science law, but asserts that as it applies to her or to the acts charged against her it infringes upon her constitutional rights and that there is no relation between the requirements of the basic science law and the protection of the public as applied to her situation.

With the defendant's contention we cannot agree. It is essential to the public health and safety that persons who, for compensation, are suggesting, recommending, or prescribing medicine or treatment for the correction or cure of human ailments have a basic understanding of the subjects required by the basic science law. In our opinion it is within the police power of the state to so require. According to the information lodged against her, the defendant induced women to come to lectures for which she charged a fee and for those who had menstrual troubles she suggested and recommended tablets which she had for sale for correction and cure of their affliction. It is our view that her conduct came squarely within the basic science law and that the requirements of that law are germane to the safety and health of the public in the treatment of such ailments as those for which she sold and recommended her tablets and medicines. Such being the case, no constitutional right of the defendant is infringed upon.

It is our opinion that the question certified to us by the trial court should be answered in the affirmative and that the court properly overruled the demurrer to the information.

Olivia Chiropractor Pleads Guilty

State of Minnesota vs. Hans C. Hanson

On January 29, 1938, Hans C. Hanson, sixty-two years of age, entered a plea of guilty to an information charging him with practicing healing without a basic science certificate. Hanson's plea of guilty was entered before the Honorable G. E. Qvale, Judge of the District Court at Willmar. The Court, upon being advised that Hanson had closed his office and taken his signs, sentenced the defendant to pay a fine of $50.00 plus court costs of $11.00.

The investigation made by the Minnesota State Board of Medical Examiners disclosed that Hanson opened an office at Olivia in October, 1937, for the practice of chiropractic. Hanson has no license to practice any form of healing in the State of Minnesota or elsewhere. He had a diploma on his office wall dated December 5, 1914, from the Palmer School at Davenport, Iowa. He admitted, however, that he had only taken a one-year course to obtain the diploma and that his preliminary education was limited to the eighth grade. He stated that after his graduation from the Palmer School, he practiced chiropractic for fifteen months at Sydney, Montana, and returned to his home at Hutchinson, Minnesota. He also stated that in 1919, when the Minnesota chiropractic law was passed, he was farming. Shortly before opening his office at Olivia, Hanson stated that he took a one month postgraduate course at the National College in Chicago. Hanson used no pretext about practicing, having the chiropractic sign on his door and also one on the outside of the building where he was located. He also ran a card in the *Olivia Times*.

The Medical Board wishes to acknowledge fine cooperation from Mr. Russell L. Frazee, County Attorney of Renville County.

The Zinc Sulfate Spray for the Prevention of Poliomyelitis

The successful use of a zinc sulfate spray in the prevention of experimental poliomyelitis in monkeys by Armstrong, Sabin, Schultz and their co-workers has stimulated much interest in its effectiveness as a preventive of the disease in human beings. Schultz demonstrated at Stanford University that in the experimental infection a solution containing 1 per cent of zinc sulfate, I per cent of pontocaine and 0.5 per cent of sodium chloride in distilled water is most effective in the monkey. The use of this technic in the human being has been too variable and uncontrolled to permit even an approximate estimate of its value. Dr. J. C. Geiger, the director of public health of San Francisco, and his distinguished committee have recommended that the use of this spray must be strictly limited until the proper technic has been worked out. (J.A.M.A., Sept. 18, 1937, p. 958)

OF GENERAL INTEREST

Dr. W. A. Brand of Redwood Falls has been reappointed to the State Board of Health.

* * *

Dr. Walter P. Gardner has assumed charge as superintendent of the Anoka State Hospital.

* * *

Dr. R. R. Hendrickson of Wadena has been named resident physician of the St. Cloud reformatory, effective February 1.

* * *

Dr. G. H. Olds of Waseca was elected chairman of the Waseca County District Scout Committee for 1938 at the district annual meeting held on January 27.

* * *

Dr. E. H. Rynearson of Rochester was elected chairman of the Zumbro Valley District Boy Scout Committee at the recent annual meeting of the group.

* * *

Dr. Z. E. House, who recently retired from government service, has returned to Cass Lake after a three months' vacation in Florida, and will enter private practice.

* * *

Dr. Walter S. Neff, who has been practicing medicine in Boston, has joined the staff of the Lenont-Peterson Clinic, Virginia, Minnesota, as head of the division of internal medicine.

* * *

Dr. Olga S. Hansen of Minneapolis spoke on "The Medical Profession as a Career for Women" at a lecture-tea for women students of Gustavus Adolphus College at St. Peter recently.

* * *

Dr. Leo Hilger of Saint Paul was elected president of the advisory board of St. Joseph's Hospital at its annual meeting, succeeding Dr. W. C. Carroll. Dr. William Kennedy was named to the board for a five-year term.

* * *

Dr. Joseph F. Malloy, associated with the Bratrud Clinic of Thief River Falls, was recently appointed Soo Line surgeon. Dr. Edward Bratrud also will continue to serve as surgeon for the company as he has for a number of years.

* * *

Dr. and Mrs. A. R. Ellingson of Detroit Lakes have gone to New Orleans, where Dr. Ellingson is taking a six weeks' course in surgery and x-ray diagnosis at the University of Tulane. They expect to return to Detroit Lakes about April 1.

* * *

Dr. Henry Porter Johnson of Fairmont celebrated his eighty-third birthday on February 3. Dr. Johnson has practiced medicine for fifty-nine years, thirty-eight of which have been spent in Fairmont, and is still actively engaged in the practice of his profession.

* * *

A special program of lectures and demonstrations in surgery and medicine will be held in Rochester under the direction of The Mayo Foundation from March 28 to April 1, inclusive. Symposiums on gastric diseases, diseases of children, cardiology, urology and backache, and conferences on roentgen, radium and physical therapy will be included. Visiting physicians are invited to attend.

* * *

The Foundation Prize of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, consisting of $500, is open to internes, residents, graduate students and doctors of medicine practicing or teaching the specialty. Manuscripts limited to 5,000 words should be submitted before June 1, 1938, to the secretary, Dr. James R. Bloss, 418 Eleventh Street, Huntington, West Virginia.

* * *

Dr. Paul O'Leary and Dr. G. B. New of Rochester, attended the International Postgraduate Medical Assembly of Southwest Texas in San Antonio in January. Dr. O'Leary spoke on the treatment of syphilis and dermatological conditions. Dr. New also attended the meeting of American Association of Plastic Surgeons in Dallas and Houston, and a sectional meeting of the American College of Surgeons in Houston. He appeared on the program at each of these meetings.

* * *

Dr. J. C. Litzenberg, Professor of Obstetrics and Gynecology at the University of Minnesota, presented a paper on "What is Good Care for Mothers and Babies" before the Conference on Better Care for Mothers and Babies held by the Children's Bureau of the United States Department of Labor, in Washington, January 17, 1938. Others from Minnesota who attended were Dr. Ruth Boynton, Director of the Student Health Service, University of Minnesota, Dr. E. C. Hartley, Clinical Instructor of Obstetrics and Gynecology, University of Minnesota, and Dr. A. J. Chesley, secretary of the Minnesota State Board of Health.

* * *

The Third Annual Postgraduate Institute, offering an intensive and interesting study of the Diseases of the Digestive Tract, will be conducted by The Philadelphia County Medical Society from March 28 to April 1, inclusive. The program to be held in the Bellevue-Stratford Hotel, Philadelphia, has been designed to meet the needs of all members of the profession, but particularly those in general practice.

Physicians from fourteen states having attended last year's institute, an invitation to attend the 1938

session has been extended to the members of all county societies. The only charge is a $5.00 registration fee to cover the Institute's expenses. Additional information may be secured from your County Society or from the Philadelphia County Medical Society, 21st and Spruce Streets, Philadelphia, Pa.

* * *

The medical staff of the Menninger Clinic will conduct its fourth annual Postgraduate Course on *Neuropsychiatry in General Practice,* April 25 to 30, inclusive, at the Menninger Clinic, Topeka, Kansas. The course this year will include a brief introduction to the fields of neurology and psychiatry and a specific application of this knowledge to the large group of cases of psychoneuroses, psychoses and psychogenic and neurological disorders which every physician meets in his daily practice. Suggestions made by those who took the course last year have been embodied in this year's program in order to make it applicable to the most common practical problems of the physician.

As in previous years, several guest speakers, prominent in the fields of neurology and psychiatry, will appear at the evening sessions of the course.

* * *

The American Physiotherapy Association has announced a Vocational Service in providing trained physiotherapists for hospital and office positions. The Association was organized very soon after the close of the World War, the charter members being former Reconstruction Aides in service. Since then the membership has increased to more than 800. The present requirements for membership are: 1. One year's practice in physical therapy within two years of graduation from an approved school of physical therapy. 2. An approved course in physical therapy of not less than nine months, following graduation from a school of nursing or physical education which meets the requirements of the individual states. These requirements have been approved by the Council on Medical Education and Hospitals of the American Medical Association. The object in having these qualifications for membership is to provide for the hospitals, schools for crippled children, and offices of physicians, trained physiotherapists who are able to follow the physicians' orders intelligently and thoroughly.

One of the purposes of the American Physiotherapy Association is to "coöperate with and work only under the prescription of members of the medical profession."

Further information may be obtained by writing to Miss Edith Monro, 483 Beacon Street, Boston, Massachusetts.

The A.M.A. Convention Tour

According to latest reports physicians and their families are evincing a keen interest in the arrangements made for a convention tour of America en route to and returning from the San Francisco convention.

The "See America" movement by deluxe special trains is endorsed by approximately twenty-five State medical societies. It presents an opportunity for members and their families to join with their colleagues from other states, and enjoy the facilities and service of deluxe special trains, and at the same time visit the many scenic attractions of our western states.

Many physicians, completely immersed in their practices, have hesitated to take such an extended vacation heretofore but now the fact of the A.M.A. convention and the attractiveness and economical features of this travel program have brought such a trip within the realm of desirable possibilities.

The all-inclusive price is unusually low because of the coöperation of so many medical societies. An attractive folder, describing these travel arrangements, may be obtained through the secretary's office or the Transportation Agents, The American Express Travel Service, 723 Marquette Avenue, Minneapolis, Minnesota.

* * *

State Meeting

The fine program arranged for the 85th Annual Meeting of the Minnesota State Medical Association at the Hotel Duluth in Duluth is prompting several special societies to hold their own annual gatherings in conjunction with the state meeting.

Dates for the assembly are June 29 and 30 and July 1.

The Northwest Pediatric Society, which is bringing one of the distinguished speakers scheduled for the regular program, will adopt the program of the pediatrics session for its own annual session. Dr. C. Anderson Aldrich of Winnetka, Illinois, is the speaker to be sponsored by the pediatricians. His subject will be, "Some Practical Points in the Management of Nephritic Children."

Other special societies and sectional groups who will finance speakers for this meeting include the Society of Internal Medicine, the Radiological Society and the Northern Minnesota Medical Association. Their speakers are respectively Dr. E. K. Marshall of Johns Hopkins, Dr. Hollis Potter of Chicago and Dr. Philip Lewin of Chicago. The Minnesota Society of Ophthalmology and Otolaryngology was of assistance in securing Dr. Edward Jackson of Denver for the program. Dr. Roland Cron of Milwaukee, Dr. Irvin Abell of Louisville, Kentucky, president-elect of the American Medical Association, Dr. Carl Meyer of Chicago, and Dr. Howard Haggard, noted writer and lecturer of Yale, were secured by the Committee on Scientific Assembly.

The completed program provides for extensive exhibits and demonstrations during morning and afternoon exhibit periods. Otherwise all sessions will be held in one lecture hall, the ballroom of the hotel, with guest speakers as features of each morning and afternoon session.

Doctor Haggard will talk to the doctors at the banquet Thursday night and he will also be principal speaker at a meeting to which the public will be invited at the Lyceum Theater in Duluth.

HOSPITAL NEWS

Dr. C. H. Schroder of Duluth was chosen chief of staff of St. Luke's Hospital at the recent annual meeting of the hospital staff.

Other staff officers named are: Dr. A. G. Athens, vice-chief of staff; Dr. S. H. Boyer, Jr., secretary; Dr. W. N. Graves, chief of surgery; Dr. R. L. Nelson, chief of medicine; Dr. R. J. Moe, chief of obstetrics; Dr. M. F. Fellows, chief of eye, ear, nose, and throat; Dr. R. E. Nutting, chief of pediatrics; Dr. A. H. Wells, chief of staff, laboratory section, and Dr. R. M. Mayne, chief of staff, x-ray section.

* * *

The Minnesota Association of Hospital, Medical and Institution Librarians held a luncheon meeting Saturday, February 5, 1938, at the Women's City Club in Saint Paul with thirty-three people present. Elizabeth Jensen of the St. Peter State Hospital and Mildred Schumacher of the Rochester State Hospital reported on the usability of the books of Temple Bailey and Mary Roberts Rhinehart respectively. Mary Heenan of the School for the Blind at Faribault described her work and dwelt in some detail upon the "Talking Books" and the government arrangements for the use of them by the blind people in this district. Mrs. Stella H. Amass, Director of Psychiatric Nursing in Minnesota, spoke upon the various types of patients to be found in hospitals and institutions, using as her title "The Librarian's Approach to the Patient." The next meeting will be at the time of the meeting of the Minnesota Hospital Association in May.

* * *

Drs. Edward Schons and J. P. Medelman announce the completion of the installation of a 1,200,000-volt, constant potential roentgen therapy apparatus which took nearly two years to construct in the Charles T. Miller Hospital of Saint Paul. This equipment was built especially for the hospital, and is considered the largest and the most advanced of its kind. It will be used primarily for the more adequate and efficient treatment of deep-seated tumors. The high voltage and filtration used will yield a radiation of high quality and penetrating power, permitting homogeneous irradiation of deeply situated tumors. Lower voltage equipment has also been installed and will be used as heretofore where that type of irradiation is indicated, as will also radium.

The Charles T. Miller Hospital has constructed a special building and made alterations in the adjacent wing, in order to accommodate the equipment and provide for needs incidental to the treatment of patients. The giant steel and porcelain tube is surrounded by lead 4 inches thick to prevent escape of radiation into the treatment room except through the treatment portals. Adequate protection of the personnel has been provided for with concrete walls 3 feet thick. Provision has been made for measuring equipment, indicating the quality and quantity of the radiation used.

In Memoriam

De Witt Clinton Jones

1868-1937

DR. D. C. JONES, Saint Paul, was born January 19, 1868, in Saint Paul, his parents having been early settlers. His aunt, Cleopatra Irvine, born in 1844, is said to have been the first white female child born in Saint Paul, at which time Minnesota was part of Wisconsin Territory.

Dr. Jones received his primary education in Saint Paul, and later attended De Vaux University, Toronto. In 1890 he was granted a degree in midwifery by the Toronto General Hospital, and the following year passed written examinations entitling him to diplomas from the Toronto, Victoria and Queen's Universities and the Trinity Medical College.

Returning to Saint Paul, Dr. Jones served his internship at the City and County Hospital in 1891 and 1892. Granted his license to practice in Minnesota in 1892, he opened an office at Seven Corners.

During the Spanish-American war, Dr. Jones served as contract surgeon at Fort Snelling and in 1911 was made First Lieutenant in the Medical Reserve.

For ten years he was coroner of Ramsey County. During this period he organized the Minnesota Coroners Association and was instrumental in revising laws relating to the duties of coroners.

Always active in politics, Dr. Jones was a founder and organizer, in 1895, of the first Democratic Club in Saint Paul. He was a member of the Ramsey County Medical Society, the Minnesota State and American Medical Associations. He was a member of the Masonic order, the Modern Woodmen and the Odd Fellows. He was also a member of the Episcopal Church. At Norwood, Minnesota, on August 22, 1908, Dr. Jones married Fannie Trocke, a well known business woman of Saint Paul. He is survived by his widow.

John Thomas Rogers

1867-1938

DR. JOHN T. ROGERS, for many years one of the outstanding surgeons of Saint Paul, died very suddenly at his home on January 2, 1938, at the age of seventy.

Born in Woodford County, Kentucky, July 18, 1867, of Kentucky stock, he received his academic education at Transylvania University. He moved to Saint Paul with his parents in 1886, and was temporarily employed in a haberdashery shop soon after his arrival. His ambition to become a doctor was made possible by his acquaintance with Dr. Charles A. Wheaton, who was then one of the leading surgeons in Saint Paul. Employment in Dr. Wheaton's office enabled him to attend the medical school at the University of Minnesota and during his student days he assisted Dr. Wheaton at emergency operations performed in out-

lying districts. Following his graduation from the University Medical School in 1890, Dr. Rogers continued his association with Dr. Wheaton and became what might have been termed a resident surgeon at the City and County Hospital in Saint Paul.

Upon Dr. Wheaton's retirement from practice in 1906, Dr. Rogers became associated with Dr. A. R. Colvin until 1915, when this partnership was dissolved and he took Dr. Harry B. Zimmermann into partnership.

Dr. Rogers was largely responsible for persuading Mrs. Charles T. Miller, the widow of Charles T. Miller of Saint Paul, to donate funds for the construction of a hospital in memory of her husband. Permission was obtained during our participation in the World War to begin construction of the hospital now known as the **Charles T. Miller Hospital** with the idea that the hospital would, upon completion, be temporarily used by the United States government. The government never used the hospital and it was necessary to obtain additional funds for equipment. This was accomplished partly by the assistance of a group of St. Paul physicians who formed the Miller Clinic in 1919. Dr. Rogers was a member of this clinic group until it dissolved in 1934. During the early days Dr. Rogers did most of his work at St. Luke's Hospital, being frequently called to operate in outlying cities. With the establishment of the Miller Hospital he became chairman of the Board of Trustees and Chief of Staff of the hospital, positions he held until his death.

Dr. Rogers was a younger member of a group of surgeons who, in the eighties and nineties, made Saint Paul a surgical center of the Northwest. A most lovable character, who inspired immediate confidence, Dr. Rogers enjoyed an enviable reputation and practice. A student rather than a scholar, he did not make numerous contributions to surgical literature. He had an almost uncanny ability to absorb minute details of operative technic by observation. He made many visits to clinics in this country and abroad for self-betterment.

During Dr. Rogers' more than forty-seven years of practice, he served as president of the Minnesota Academy of Medicine in 1901 and as president of the Minnesota State Medical Association in 1915. He was also a member of the American College of Surgeons and of the Ramsey County Medical Society and the Minnesota State and American Medical Associations.

Dr. Rogers is survived by his daughter Mrs. Jerome Helpern of Saint Paul, having been preceded in death a few years ago by his wife.

Philemon Roy

1869-1938

DR. PHILEMON ROY, Saint Paul, died of coronary disease, January 21, 1938, while on vacation in McAllan, Texas.

Dr. Roy was born at St. Anaclet, Quebec, December 13, 1869, of French parents, the third of a family of fifteen children. He received his primary education at the College of Remouski in the Province of Quebec. He received his M.D. from the University of Minnesota in 1896.

After practicing a few years at Pierz, Minnesota, he took three years of postgraduate study in Paris, Vienna and Berlin. Upon returning to the United States he served one year as assistant to the chief surgeon in the French Hospital at San Francisco. In 1902 he began general practice in Saint Paul with offices in the Grand Opera House Building, in 1919 moving to the Hamm Building.

In 1907, Dr. Roy married Ada Cheverton of Rich Hill, Missouri. He is survived by his widow, a daughter Germaine, and a son, Dr. Philemon C. Roy, who has been associated with him the past two years.

Dr. Roy was a member of the Elks, the Maccabees, L'Union Francois, the Woodmen of the World and a life member of the Saint Paul Athletic Club. He was a member of the medical staffs of Bethseda, St. Joseph's and St. John's Hospitals. He was a member of the Ramsey County Medical Society, of which he was vice president in 1937, and of the Minnesota State and American Medical Associations.

Gonorrhea and Sulfanilamide

In view of the widespread interest in sulfanilamide and related compounds in the treatment of gonorrhea, the work of Johnson and Pepper (Weekly Roster and M. Digest, 33:465, (Dec. 11) 1937) on this subject is of interest. Twenty-four patients were given a benzyl sulfanilamide (*p*-benzylamino-benzene-sulfonamide), a drug as yet not on the market in this country, and seventy-five were given sulfanilamide (thirteen were given courses of both drugs). Of the twenty-four patients given this benzyl sulfanilamide, fourteen were treated for ten consecutive days with a minimum ten-day dosage of 600 grains. Only two of the entire group seemed to be improved. Of the seventy-five patients given oral daily divided doses of sulfanilamide, sixty-four were seen sufficiently long to analyze the results. Of this group more than half represented failures, based on an arbitrary ten-day standard. Fifty-five per cent of the sulfanilamide group and 50 per cent of the benzyl sulfanilamide group showed toxic symptoms. As a result of the somewhat disappointing observations the authors feel this type of therapy should not be employed in the routine treatment of outpatient gonorrhea. This work represents an additional argument for the careful administration of this group of drugs, since they appear to be of considerable value in some cases of the disease. (Jour. A.M.A., Jan. 1, 1938, p. 51.)

Crystalline Vitamin A.

The actual isolation of vitamin A in crystalline form appeared desirable chiefly for definite confirmation of the mass of circumstantial evidence pointing to its actual chemical configuration. This isolation has now been attained as a result of a series of noteworthy investigations by Holmes and Corbert at Oberlin College. By the use of purified solvents, low temperatures and special technical precautions, it has been possible to isolate the vitamin in crystalline form from the liver oils of three different species of fish. Biologic assay indicates that the crystalline preparation has a value of approximately 3,000,000 international units per grain. The molecular weight determinations and elementary analyses of the compound correspond to a formula already suggested for the vitamin. Thus, a dietary essential which has been known for a quarter of a century has finally been obtained in a crystalline, probably pure, form. (Jour. A.M.A., Dec. 11, 1937, p. 1992.)

REPORTS and ANNOUNCEMENTS

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The general oral, clinical and pathological examinations for all candidates (Groups A and B) will be conducted by the entire Board, meeting in San Francisco, California, on June 13 and 14, 1938, immediately prior to the meeting of the American Medical Association.

Application for admission to the June 1938 Group A examinations must be on an official form and filed in the Secretary's Office before April 1, 1938.

The annual informal Dinner and General Meeting of the Board will be held at the Palace Hotel, San Francisco, on Wednesday evening, June 15, 1938, at seven o'clock. Dr. William D. Cutter, Secretary of the Council on Medical Education and Hospitals of the American Medical Association, will be the guest speaker, and the Diplomates certified at the preceding days' examinations will be introduced individually. All Diplomates are invited to attend the dinner meeting, and to bring as guests their wives and any persons interested in the work of the Board.

For further information and application blanks address Dr. Paul Titus, Secretary, 1015 Highland Building, Pittsburgh (6), Pennsylvania.

AMERICAN COLLEGE OF SURGEONS MID-WEST SECTIONAL MEETING

The Mid-West Sectional Meeting of the American College of Surgeons, including the states of Wisconsin, Minnesota, Iowa, Illinois, and Upper Michigan, will be held in Milwaukee, Wisconsin, on March 29, 30, and 31. The headquarters will be at the Schroeder Hotel. A most active Committee on Local Arrangements, headed by Dr. Carl W. Eberbach, is making excellent plans for this meeting. There will be an exceptionally interesting program consisting of clinics, scientific sessions, hospital conferences, medical motion pictures, and other features during the meeting. A visiting group of ten or twelve outstanding surgeons will be present to participate in this program.

The three-day session will be devoted to clinics, conferences and the inspection of scientific exhibits.

This meeting will be of interest not only to Fellows of the College but to the medical profession at large, as well as to hospital trustees, superintendents, nurses, and hospital personnel. Members of State Medical Associations are most cordially invited to attend. There will be no registration fee.

ASSOCIATION OF MILITARY SURGEONS

The Association of Military Surgeons of the United States will meet in Rochester for its annual convention October 13, 14 and 15, 1938. Dr. F. L. Smith of Rochester, a member of the Association, has been appointed by the Mayo Foundation to be chairman of local arrangements.

Headquarters of the Association are in the Army Medical Museum in Washington, D. C., with Major General H. L. Gilchrist, United States Army, retired, acting as national secretary.

It is expected that approximately 500 persons will attend the convention. Programs for the meetings usually include physicians from foreign countries and officials of the Army and Navy departments.

UPPER MISSISSIPPI SOCIETY

The following officers were elected at the annual meeting of the Upper Mississippi Medical Society, January 29, at Brainerd, Minnesota:

President.....Dr. H. L. Lamb, Little Falls
First Vice President .....Dr. Z. E. Kerlan, Aitkin
Second Vice President .....Dr. O. Ringle, Walker
Secretary .....Dr. G. I. Badeaux, Brainerd

WASHINGTON COUNTY

At the regular meeting of the Washington County Medical Society, February 8, two county commissioners and S. E. Gilkey, M.D., Medical Advisor to the State Relief Administration, met with us to discuss the various problems of relief.

The county commissioners were asked to state their position, inasmuch as there had been some dissatisfaction, which they did briefly. The doctors presented their problems and difficulties. The commissioners asked for questions—which were not slow in coming. After the pros and cons were gone over, it was evident that some progress toward a better understanding was undoubtedly made. After the county commissioners left, Doctor Gilkey analyzed the situation from the State Relief Administration's point of view.

Viosterol and Psoriasis

Cedar and Zon (Pub. Health Rep., 52:1580, (Nov. 5) 1937) administered massive doses of viosterol without local treatment of the lesions, dietary adjustment or any other therapeutic measure. A series of fifteen patients from 30 to 50 years of age with chronic widespread psoriasis were given from 300,000 to 400,000 units of vitamin D as viosterol. Eleven of the fifteen subjects showed complete involution of the psoriasis within six to twelve weeks' time. At the end of the period of treatment, three patients showed incipient symptoms of excessive vitamin D dosage. All the subjects exhibited an elevation in the level of blood calcium. There was a recurrence in some of the patients, though the degree of severity was much less than originally observed. Although the proposed treatment would appear to be safe, the authors suggest not only that there may be a smaller effective dose of viosterol but also that certain accompanying products of the irradiation of the ergosterol may be the potent factor. (Jour. A.M.A., Jan. 8, 1938, p. 133.)

PROCEEDINGS of the MINNESOTA ACADEMY of MEDICINE

Meeting of December 8, 1937

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, December 8, 1937. Dinner was served at 7 o'clock and the meeting was called to order at 8:10 by the president, Dr. E. M. Jones.

There were forty-nine members present.

Minutes of the November meeting were read and approved as read.

The following officers were elected for the year 1938:

President.....R. T. LaVake, Minneapolis
Vice President.....Carl B. Drake, St. Paul
Secretary-Treasurer.....A. G. Schultze (reëlected)

The scientific program consisted of a symposium on Syphilis, and the following papers were presented:

1. Syphilis as a Social Problem....Dr. S. E. Sweitzer
2. Immunobiology of Syphilis....Dr. H. E. Michelson
3. Primary Syphilis .....Dr. John Butler
4. Visceral Syphilis.....Dr. H. L. Ulrich
5. Asymptomatic Neurosyphilis.....Dr. Paul O'Leary
6. Syphilis as Seen in the Human Clinic Thirty-five Years Ago .....Dr. Frank Wright

---

SYPHILIS AS A SOCIAL PROBLEM*

S. E. Sweitzer, M.D.
Minneapolis

It may seem superfluous to discuss syphilis as a social problem before a medical group, but recently Dr. Thomas Parran, Surgeon General of the United States Public Health Service, started a campaign against syphilis and the social diseases and has asked for coöperation from the various states. Here in Minnesota the President of the State Medical Society appointed a committee to coöperate in this work with the United States Public Health Service.

The difficulty of the control of a disease like syphilis can be shown by the success that we have in this country in eradicating smallpox. Van Etten[3] in a recent article mentions that we still have 40,000 cases of smallpox annually and this is a preventable disease. Vaccination and revaccination could eradicate it in a few years. We have no vaccine for syphilis and must endeavor to work on different lines. No one will deny that syphilis presents a tremendous problem and an endeavor will be made to examine this problem and to suggest how we can aid here in Minnesota.

With the publicity given the Surgeon General's attack on syphilis it has become popular to mention this disease in the newspapers and magazines and over the radio. For a time the public may become syphilis minded but a warning must be given in regard to syphilis control, for when the fanfare of publicity ceases, any permanent and effective control of the disease must be accomplished by steady and continuous efforts of the medical profession.

From reading many of these news and magazine articles and from some of the statements made by men interested in the subject, one might assume that syphilis is on the increase. Let us see what has happened here in Minnesota in regard to the incidence of syphilis.

The first concerted attack upon syphilis was as a war measure. Minnesota was up among the leaders at that time and after the War this anti-syphilis campaign never was dropped. In most states, due to lack of funds or other causes, the war on syphilis was allowed either to be dropped entirely or was greatly limited in scope. As a result of our efforts here there has been a steady decrease in the incidence of syphilis in Minnesota. Many of you have read articles recently in which the incidence of syphilis is given as high as 10 per cent of the population. This is not true in Minnesota.

The following table will show a steady decrease from a high in 1925. The year 1918, being the first year, of course did not show many cases reported.

TABLE I. VENEREAL DISEASE CASE REPORTS—
State Department of Health, Division of Preventable Diseases
Minnesota—1918-1936

Year	Syphilis
1918	1801
1919	3551
1920	4422
1921	4814
1922	4291
1923	4779
1924	4809
1925	5147
1926	4871
1927	4938
1928	4438
1929	3983
1930	4104
1931	4199
1932	4033
1933	3824
1934	4071
1935	4224
1936	3379

The latest comparison is shown in Table II, where there is a slight increase this year in reported cases. This is more than likely due to the recently inaugurated campaign against syphilis with its attendant publicity. As a result, while in the first half of 1936 there were 39,713 Wassermanns sent in, in the same period of 1937 there were 50,570 sent in. No wonder a few more cases were discovered and most of these were from Minneapolis.

Dr. H. G. Irvine, in a personal communication, stated that in 1936 out of over 83,000 Wassermanns only about 6 per cent were positive. Diehl[1] over a two-year

*From the Department of Dermatology and Syphilology, Minneapolis General Hospital, Dr. S. E. Sweitzer, Chief.

period of observation of 5,000 students at the University of Minnesota was able to find only ten cases of syphilis.

TABLE II. VENEREAL DISEASE—CASE REPORTS

First Two Quarters 1936

Syphilis

State	Minneapolis	Duluth	Total
1089	466	161	1716

First Two Quarters 1937

State	Minneapolis	Duluth	Total
1103	513	138	1754

In our neighboring state of Wisconsin, Lorenz[2] recently stated that the incidence of syphilis in the general sick does not exceed 3 per cent and that the admission rate of late syphilis to State Hospitals has been reduced over 60 per cent in the last ten years.

Syphilis for many years has been decreasing. It is becoming increasingly difficult to obtain sufficient active cases for teaching purposes in many of our Universities. Syphilis also has decreased tremendously in private practice and especially so among men who specialized in the disease.

Table III, below, will show the decrease at the Minneapolis General Hospital where we treat more cases than are treated in any clinic in the state.

TABLE III.

	Primary	Secondary	Tertiary	Prenatal	Total
*1937	10	19	174	13	216
1936	15	32	217	11	275
1935	27	66	297	7	397
1934	31	78	268	26	303
1933	29	113	269	33	444

*Over a ten months period.

With these figures from our own state and from Wisconsin it seems that we are making a successful attack upon syphilis and have been doing so for many years. This success by no means should cause us to lessen our efforts but should spur us on to a greater and more effective attack upon the disease.

Suggestions for Further Efforts

1. The more widespread use of the Wassermann reaction as a routine in general medicine.
2. Early and routine Wassermanns upon all pregnant women. An early discovery of syphilis in a pregnancy can practically eliminate prenatal syphilis.
3. Greater facilities for dark field examinations.
4. Better social service work in looking up sources and contacts.
5. Special attention and close follow-up as to continuous treatment should be given to food handlers, pregnant women, prenatal syphilitics and prostitutes.
6. Continued education of the medical profession in regard to long and continuous treatment of syphilis.

PRIMARY SYPHILIS

John Butler, M.D.
Minneapolis

After inoculation of the broken skin or mucous membrane with the spirochete pallida, a syphilitic incubation period begins which lasts approximately seven weeks. During this incubation period there is a gradually increasing general spirochetal invasion of the tissues through the blood stream. One to two weeks later (eighth or ninth week of the disease) the reaction in the tissue caused by localized foci of spirochetes produces the eruptive manifestations of the disease.

During the first three weeks of the incubation period there is no evidence to the patient or the physician of the impending disease. Between the third and fourth weeks the primary lesion or chancre appears.

A week or ten days after the appearance of the chancre, the regional lymph glands enlarge and show the characteristic pea- to nut-sized round, hard, freely movable, painless, nodular swellings. During the ensuing three weeks the lymph glands in distant parts of the body become involved.

The systemic symptoms in primary syphilis are usually slight or absent and are of no diagnostic import. More frequently they are present and intensified in the secondary or eruptive stage of the disease. When present, they may show as anemia, fever, headache, insomnia, arthritic pains, etc.

Our conception of the course of early syphilis has been changed as a result of the discovery that the lymph and blood of animals and humans infected with syphilis may contain the spirochetes a few hours after infection and may be found in the blood stream for an indefinite time—months or years—in latent Wassermann-negative cases. This brings to the fore the potential danger of transfusion syphilis from latent syphilitic donors.

A clinical diagnosis of the incipient primary lesion is generally impossible and uncertain and the fully-developed chancre, to the unpracticed eye, is often undiagnosed.

The chancre, like other manifestations of syphilis, varies in appearance according to the location, the structure and reaction of the tissue in which it is situated. It may assume different appearances as to shape and size, surface secretions, and multiplicity. It may, or may not, be indurated. We read in many current textbooks on syphilis that the primary lesion presents a fairly definite appearance, the induration of the sore receiving special consideration in formulating a positive diagnosis. As a matter of fact, there are clinical varieties of the chancre that show no appreciable induration on the most careful examination.

Prior to the discovery of the spirocheta in the initial lesion of primary syphilis, the clinician's attitude was that of watchful waiting and observation.

An early diagnosis of primary syphilis depends on finding the spirocheta pallida in the early chancre before the organisms have been disseminated and local-

ized in large numbers in the denser tissues throughout the body, before profound pathological changes have taken place. The Wassermann test is of no diagnostic value during the first five weeks of the disease, as it is usually negative then.

If the chancre has been treated locally with antiseptics, especially mercurials, it is a waste of time to attempt to recover the spirocheta pallida from the lesion. By stopping the local treatment, they may or may not be demonstrated after a week or ten days. In such cases, aspiration of the adjacent lymph nodes may be successful. The dark field method should be used instead of the India ink or staining method.

The possibility of aborting or curing a large percentage of primary syphilis by early diagnosis (before the sixth week of the disease) when the Wassermann is usually negative, should not be overlooked; and immediate intensive treatment should be a matter of persuasive interest to the physician of today. Every day lost in diagnosis and treatment is of vital importance to the patient. The patient receiving early treatment, when the primary lesion is not more than a week or ten days old and with a negative Wassermann, has a 25 per cent better chance for a cure than a patient with secondary syphilis.

VISCERAL SYPHILIS

HENRY L. ULRICH, M.D.
Minneapolis

I am detailed to speak on visceral syphilis. With the limited time at my disposal, I would like to confine myself to one type of visceral syphilis—namely aortitis and its sequences. Syphilis of the stomach is rather rare and more or less problematic. Syphilis of the liver is likewise not so common and perhaps not so problematic. There is no organ in the body exempt from syphilitic invasion except the ovary. Wartin claims he has never seen the ovary involved.

It is thirty-two years since the Treponema palida was discovered. It is thirty years since salvarsan was first used. The curative effect of standard syphilitic therapy is as high if not higher than any other treatment for any other disease, surgical or medical. Why is it there is so much visceral syphilis in our population today? Let me just hint at several factors which may be involved in the explanation of this paradox. There is the psychology of our people who still cling to the attitude that syphilis is a disgrace rather than misfortune. This is a cause for a lag in getting early treatment. The high cost of therapy and the time element hinder the result. That leads me to the statement that the treatment of 60 per cent of all venereal disease is in the hands of 5 per cent of the physicians. In other words, the treatment has become highly specialized. Students of this phase of the problem are beginning to think that this is a mistake. The treatment of syphilis should be in the hands of the family physician and general practitioner. I am aware the last statement has its controversial point. I have stated it merely to show the trend of things in the larger problem.

Potentially speaking, every syphilitic may develop aortitis. It usually manifests itself in the most efficient years. It is the commonest lesion found at the post mortem table. It is the most deadly visceral lesion. It is one of the most avoidable complications if proper treatment is instituted and carried out in the primary stage. In its uncomplicated state, it is extremely difficult to diagnose. It is this last feature I wish to elaborate and emphasize.

In 1885 Dohle definitely established the difference between syphilis and atherosclerosis of the aorta. It took some eighteen years before it was definitely accepted by his German colleagues. It is only in recent years that some semblance of order is establishing itself regarding aortitis as a clinical problem. Langer in Germany reports 23,105 necropsies on syphilitics of which 70 to 80 per cent showed evidence of involvement of the aorta.

The clinical grouping is seen in Table I. The standard of diagnosis usually given is that by Carter and Baker (Table II). A year later Moore, Danglade and Reisinger modified this as shown in Table III.

TABLE I. CLINICAL CLASSIFICATION

1. Uncomplicated Aortitis. Latent 4.9 to 49.5 per cent in all types of aortitis (living).
2. Aneurysm. Latent syphilis 1.2 per cent, active 11.8 per cent, postmortem 27.7 per cent.
3. Aortic Valvulitis. Living 2.7 per cent to 4.1 per cent, postmortem 24.7 per cent to 36.5 per cent.
4. Coronary osteal involvement. Postmortem 19.9 per cent to 33.3 per cent.
5. Combinations of 1 with either 2 or 3 or 4.
6. Aortitis or its complications associated with lesions of the heart unrelated to syphilis, i.e., hypertension (essential or renal), coronary disease (atherosclerosis), valvulitis due to rheumatism; subacute bacterial endocarditis (rare); pericarditis (rare).

The standard for the diagnosis of aortitis in general is usually that given by Carter and Baker.[1]

TABLE II. STANDARD FOR DIAGNOSIS OF AORTITIS
(Carter and Baker)

1. The history of a relative abrupt and unexpected onset of circulatory embarrassment.
2. The presence of a positive Wassermann reaction.
3. A demonstrable increase in the retromanubrial dullness in the second interspace and a change in the tonal qualities of the second aortic sound. The fluoroscopic evidence of aortic dilatation.
4. An absence of the signs of mitral disease connating rheumatic infection.
5. The history of paroxysmal dyspnea, often nocturnal.
6. The history of pain, particularly paroxysmal pain.
7. Progress in cardiac failure.

If any five of these seven criteria are present, a diagnosis of cardiovascular syphilis can be made.

Moore, Danglade and Reisinger[2] give as criteria for an uncomplicated aortitis diagnosis any three of the following seven criteria.

TABLE III. STANDARD FOR DIAGNOSIS OF AORTITIS
(Moore, Danglade and Reisinger)

1. Teleroentgenographic and fluoroscopic evidence of aortic dilatation.
2. Increased manubrial dullness.
3. A history of circulatory embarrassment.
4. A tympanitic, bell like, tambour, accentuation of the second aortic sound.
5. Progressive cardiac failure.
6. Substernal pain.
7. Paroxysmal dyspnea.

TABLE IV. A COMPARISON OF THE CORRECTNESS OF THE CLINICAL AND PATHOLOGICAL DIAGNOSIS OF SYPHILITIC AORTITIS IN ONE HUNDRED AND FIVE CASES SO DIAGNOSED AT NECROPSY[2]

	Total Cases	Syphilitic Aortitis		Diagnosis could have been suspected on basis of physical findings			Diagnosis obscured by other cardiovascular lesions	Heart and aorta thought clinically normal	Patient too ill for adequate examination
		Definitely diagnosed	Suspected	Signs	Symptoms	Both			
Medical Service	63	4	12	12	2	9	9	11	4
Surgical Service	42	0	1	5	4	3	3	23	3
	105	4	13	17	6	12	12	34	7
Percentage of of Total		16.2			33.3		11.4	32.3	

TABLE V. THE CORRECTNESS OF THE CLINICAL DIAGNOSIS OF SYPHILITIC AORTITIS AS INFLUENCED BY THE CAUSE OF THE FATAL ILLNESS[2]

	Total Cases	Diagnosis correctly made or suspected	Diagnosis might have been made	Diagnosis obscured by other cardiac findings	Diagnosis missed (Impossible to make. ?)
Fatal illness related to syphilis	24	6 (25%)	7 (29%)	5 (20%)	6 (24%)
Fatal illnesses unrelated to syphilis which if diagnosed was an incidental finding	81	10 (12%)	29 (35%)	7 (8%)	35 (43%)

Moore et al[2] made a study of 105 cases of aortitis uncomplicated by aortic regurgitation or aneurysm. They worked backward from the postmortem material to the clinical findings (Table IV). From a study of this chart only four of the 105 were definitely diagnosed and thirteen were suspected, making a total of 16.2 per cent. There were twenty-three cases where the diagnosis could have been suspected on the bases of physical signs, and incidence of 33 per cent. There were 12 cases where the diagnosis was obscured by other cardiovascular lesions—11.4 per cent. There were thirty-four in which the heart was considered normal clinically—32 per cent, and there were seven cases in which the patient was too ill for adequate examination.

In the cases which were correctly diagnosed or suspected, either the classical signs of widened manubrial dullness, pulsation in the suprasternal notch, an aortic systolic murmur or an altered tympanitic, bell-like quality of the second sound, or the symptoms of substernal pain, dyspnea on exertion or paroxysmal nocturnal dyspnea, or both signs and symptoms were present. In the thirty-five cases which could have been diagnosed, these symptoms and signs were present in some degree.

The significance of these findings were entirely disregarded by the clinicians. The majority of these patients were admitted for an acute illness unrelated to syphilis. Judging, however, from the extent of the lesions at autopsy, they suggest that the clinical diagnosis was not necessarily impossible.

Table V gives the correctness of the clinical diagnosis of syphilitic aortitis as influenced by the cause of the fatal illness.

Curiously enough hypertension which can confuse the picture did not make the diagnosis more difficult. In fact, more cases of aortitis with hypertension were correctly diagnosed than without hypertension.

The most recent study of uncomplicated aortitis is that by Wilson.[3] He too worked backward from the postmortem table to the clinical findings. His material consisted of 106 cases. Extensive pathological changes were found in twelve, moderate in twenty-seven and only slight in twenty-one cases. Three cases showed marked dilation; there was moderate dilation in seven, slight in ten and there was a normal sized aorta in forty cases. He agrees the physical signs adopted in the above criteria are without a doubt dependent on aortic dilation. The symptoms, however, "are by no means indisputable and the validity of ascribing certain of these symptoms to purely uncomplicated aortitis has been seriously questioned."

He quotes Keefer and Resnik who in twenty-four cases of uncomplicated aortitis never found dyspnea on exertion, nor paroxysmal dyspnea, nor signs of myocardial insufficiency. In every case where such symptoms supervened, there was some additional factor, aortic insufficiency, aneurysm, myocarditis, hyper-

TABLE VI. INCIDENCE OF SYMPTOMS IN SYPHILITIC AORTITIS[3]

	Total* Cases	Dyspnea on exertion	Paroxysmal dyspnea	Precordial pain	Congestive heart failure
With aortic insufficiency	49	49	14	10	49

Without other cardiovascular disease*	60	1	0	0	0
Totals	106	44	4	5	34

*The one patient showing dyspnea had leukemia.

tension or organic obstructive lesions. He cites Maynard, Curran and Rosen who conclude myocardial failure only ensues after some complication develops. Adequate explanation of the story of circulatory embarrassment, progressive heart failure, substernal pain, and paroxysmal dyspnea, long considered as typical of pure aortitis, has not been given. In other words, when symptoms of circulatory embarrassment occurs, the case has gone beyond the stage of simple aortic involvement, or there are complications unrelated to syphilitic aortitis which explain the symptoms. He cites sixty cases of the 106 in which an analysis of the symptoms were possible. In only one was there a record of dyspnea, and that patient had leukemia (Tables VI and VII).

Wilson's analyses which reveals that uncomplicated aortitis is an asymptomatic disease is quite correct, which leaves for our diagnosis of this condition only the physical signs. These signs must depend entirely on weakness dilatation of the aorta. If this is present, increased manubrial dullness in the second interspace, a systolic bruit at the base, or a second sound having bell-like qualities should put us on our guard. These with a history of syphilis, or a scar on the penis, or a positive Wassermann reaction makes the diagnosis fairly reliable. With the growth of x-ray technic, our finger-tips, our eyes and ears are losing their sense of accuracy. Few men will accept a diagnosis of a chest condition on the data which inspection, palpation, percussion and auscultation afford. Without the x-ray check, as it is called, our physical signs are not complete. The x-ray criterion for aortitis uncomplicated by aneurysm is usually considered either an increased density of the aorta or an increase in the width of the aortic arch. In a six-foot plate of the arch in the anterior-posterior direction two measurements are computed in estimating the diameter of the arch. The first is the distance from the widest part of the ascending aorta to the midsternal line. The second is the distance from the farthest lateral point on the knob to the midsternal line. The sum of these two is an arbitary diameter of the aortic arch. There is another computation. The width of the aorta is measured in the right oblique. The inability to visualize this frequently makes its value less than the arbitrary diameter of the arch. Between the ages of seventeen and fifty-nine in the male, this figure gradually increases from 4.6 to 6.1 cm.; in the female from 4.3 to 5.6 cm. Any variation above these figures of 0.5 cm. can be considered abnormal within 80 per cent of accuracy. Four conditions, as a rule, may produce a change in the silhouette of the arch either by dilation or by displacement of the aorta. They are syphilitic aortitis, aortic insufficiency, hypertension and arteriosclerosis. With such an array of causes the x-ray is quite limited in its usefulness. It can tell us there is a change in the aorta. To sift out these components, we must resort to the history, physical findings and laboratory data. In uncomplicated aortitis this is an extremely difficult task. Since it is the stage in which prevention of aneurysm or valvulitis or both is possible, it is most important that it be recognized. Statistics show that very few cases treated at this period go into the symptomatic phases of aortitis. Furthermore, statistics show that uncomplicated aortitis rarely is found in persons given the proper antisyphilitic treatment in the

chancre stage. Better still would be the eradication of the scourge of syphilis itself.

This is a public health problem. What has been done in the Scandinavian countries can be done in our own.

ASYMPTOMATIC NEUROSYPHILIS*

Paul A. O'Leary, M.D.
Rochester, Minnesota

Asymptomatic neurosyphilis is the most significant manifestation of syphilis of the central nervous system. This somewhat inclusive statement is based on the following facts: (1) asymptomatic neurosyphilis becomes clinical neurosyphilis if not sufficiently treated; (2) in the great majority of cases of asymptomatic neurosyphilis, the response to treatment is exceedingly good if treatment is adequately and intensively given; (3) by the early recognition and thorough treatment of asymptomatic neurosyphilis the development of the late forms of neurosyphilis, such as tabes dorsalis, paresis, and so forth, may be avoided, a fact which emphasizes the preventive value of adequate treatment of this complication of the disease. Accordingly, it is my purpose in this paper to discuss the incidence, the prognosis and the results of various types of treatment of asymptomatic neurosyphilis.

As the name implies, asymptomatic neurosyphilis is recognized by the finding of a positive spinal fluid test in a case in which neither clinical signs nor symptoms of neurosyphilis are present. The complication is a manifestation of syphilis in any of its various phases; and for reasons to be discussed shortly, it is divided into two groups, early and late. Early asymptomatic neurosyphilis is seen among those patients whose syphilis is of four years' duration or less, while among patients who have late asymptomatic neurosyphilis are those whose disease has been present for four years or more. As has been said, asymptomatic neurosyphilis is recognized by the obtaining of positive tests of the spinal fluid. In testing the fluid it is essential to do not only the Wassermann or flocculation procedure, but also to count the lymphocytes and other cells which may be present, to do a colloidal benzoin or colloidal gold test, and to estimate the globulin and protein content. The analysis of these five factors of the fluid permits classification of the type of invasion or involvement existing in the nervous system at the time the examination is made. Such classification is essential to an intelligent program of treatment. For example, if a patient has acute syphilis, the finding of 30 lymphocytes (normal 1 to 6) per cubic millimeter of spinal fluid with negative flocculation, globulin and colloidal tests indicates that invasion of the central nervous system has taken place. In such a case, if the Wassermann or flocculation test on the blood does not revert to negative and remain so after treatment is completed, or if it continues to remain positive during treatment, presumptive evidence is at hand that the treatment has not controlled the complication and that what was merely an invasion has now become, or is in the process of becoming, an involvement of the central nervous system. Another significant reason why all the tests of the spinal fluid are essential is that patients are encountered who have acute syphilis, and examination of their spinal fluids discloses the following: strongly positive Wassermann tests, positive globulin tests, 60 to 80 mg. or more of protein per 100 c.c., a cell count of 50 or more lymphocytes per cubic millimeter, and a Zone I or paretic type of colloidal test.* A spinal fluid which gives these findings is interpreted as a paretic type of fluid, and its presence indicates that the treatment must be carried not only beyond that given to the average patient, but also that the spinal fluid must be examined frequently during the course of treatment and several times after the fluid has become negative. This last is urged as a precaution against neurorelapse because this type of fluid is especially prone to relapse to positive.

In the late type of asymptomatic neurosyphilis, appraisal of all the factors referable to the spinal fluid is also essential for adequate management of the case, not only because examinations of the spinal fluid permit a classification which prognosticates the eventual outcome of the case, but particularly because it enables the physician, by repeated testing of the fluid, to estimate intelligently the effect of treatment on the course of the disease. As will be shown subsequently, a patient who has late asymptomatic neurosyphilis, with a spinal fluid of paretic formula, which does not lose its paretic characteristics under two or more intensive courses of treatment with arsphenamine and bismuth or mercury, should be considered a candidate for more radical therapeutic measures, such as intraspinal or fever therapy. If all of the named diagnostic tests are not done on the first examination of the spinal fluid, subsequent efforts to estimate changes in the fluid, either favorable or otherwise, will be impossible. Attention is also called to the fact that in tests of spinal fluid the cell count is the first indicator of a return to normal, and that the colloidal test is the second in order of frequency to revert to the normal side; the globulin and protein tests follow, and the Wassermann test, as a rule, is the last to become negative. Accordingly, it is recommended, in fact it is urged, that all these tests be considered each time the spinal fluid is examined, and that repeated examinations of the spinal fluid of patients with asymptomatic neurosyphilis be made during the treatment if

*From the Section on Dermatology and Syphilology, The Mayo Clinic, Rochester, Minn.

*In a normal spinal fluid the colloidal gold or benzoin test is reported as follows: 0 0 0 0 0 0 0 0 0 0 for the gold, or 000 000 110 000 000 for the benzoin. With a paretic patient the curve for gold will be reported as 5 5 5 5 5 4 2 1 0 0, whereas that for benzoin will be reported as 333 333 333 321 000. The syphilitic or tabetic curve, which is considered a favorable type of report for the neurosyphilitic patient, is recorded 0 1 2 3 3 2 1 0 0 0 for the gold, and 000 000 333 000 000 for the benzoin.

the result is to be appraised adequately. Examination of the spinal fluid should also be made at least twice yearly after the fluid has become negative. Apropos of this last statement it is acknowledged that the flocculation tests, such as the Kahn, Kline, and Hinton, are so much more valuable than the older Wassermann technics that repeated examinations of a spinal fluid which has become negative are not essential if flocculation tests of the blood are repeatedly negative.

I have already commented on the fact that asymptomatic neurosyphilis is a manifestation of acute syphilis. In the coöperative clinical studies,[1] evidence has been accumulated which shows that among 30 per cent of patients who have primary syphilis the central nervous system has already become invaded. A study of the later manifestations of the disease revealed that in secondary syphilis 35 per cent, and in 56 per cent of the patients with recurrent secondary syphilis manifestations of neurosyphilis in one or the other of its many forms were noted. This incidence in a group of patients who were not treated is highly significant, as it demonstrates that a half to a third of those who acquire syphilis are potentially neurosyphilitics. Moore[2] carried this type of study further in that he appraised the incidence of asymptomatic neurosyphilis according to the yearly duration of the disease and found that the lowest incidence occurred in cases in which the disease was of four years' duration. From the fourth year on, the incidence of the disease remains the same, about 10 per cent, while the incidence of the clinical forms of neurosyphilis steadily increases after the fourth year. This effort to control the disease by development of the defensive mechanism during the first four years of infection is to be noted in other manifestations of syphilis, and it is the reason for classifying asymptomatic neurosyphilis as the early type, which includes cases in which patients are in the first four years of the disease, and the late type, or those who have had the infection more than four years.

A discussion such as this would be incomplete without calling attention to the influence of treatment of acute syphilis on the incidence of asymptomatic neurosyphilis, as it particularly emphasizes the value of certain methods of treating the disease in its early manifestations. Among patients who received more than twenty-four injections of mercury or bismuth given by the so-called continuous system, I found asymptomatic neurosyphilis in 7.5 per cent. Among those whose treatment was inadequate, consisting of less than twenty-four injections of arsphenamine and a metal, 22 per cent had a positive spinal fluid test. If the treatment was given at irregular intervals, and with no thought to system or persistence, the incidence increased practically to 30 per cent. These data are significant in that they illustrate the fact that a sufficient amount of treatment during the acute phase of syphilis, if given intensively and by the continuous system, will cut the incidence of asymptomatic involvement of the central nervous system in late syphilis in half.

The prognosis of asymptomatic neurosyphilis is, on the whole, quite satisfactory if treatment is adequate and sufficiently intensive. My observations indicate that if both the specific and the nonspecific therapeutic measures are employed, satisfactory serologic reversal may be obtained in more than 65 per cent of these cases, and that in less than 3 per cent of the cases in which asymptomatic neurosyphilis was treated adequately by all the therapeutic measures at our command today, did clinical manifestations of neurosyphilis develop. These figures illustrate the value of adequate treatment in the prevention of serious sequelæ in the nervous system, and in the discussion on treatment attention will be called to the different methods or systems of treatment which have been proved of value.

The earlier in the course of the disease, invasion of the central nervous system is noted, the more satisfactory are the results of treatment. In the early type of syphilis, of less than four years' duration, most of the cases in which examination of the spinal fluid reveals a mild form of the disease will give evidence of a complete serologic reversal following three courses of arsphenamine and mercury. I have shown that it is the normal tendency for the fluid to revert to negative by the fourth year of the disease, so that treatment should be directed to the encouragement of this phenomenon. In those cases in which the findings on examination of the spinal fluid are of the paretic type, the incidence of favorable response is lower in both the early and late types of asymptomatic neurosyphilis, and it is in these cases that the application of the more intensive systems of treatment is warranted. In a case in which the findings on examinations of the spinal fluid are of the paretic type, and the patient has failed to give evidence of improvement following the first course of arsphenamine and bismuth or mercury, the use of intraspinal therapy of the Swift-Ellis type will double the number of cases of successful serologic reversals.

My experience with the Swift-Ellis technic has impressed me repeatedly with its outstanding value for this type of neurosyphilis, and it is to be regretted that so valuable a measure is not used more liberally in the treatment of asymptomatic neurosyphilis. One of the reasons that the method is not used more universally is perhaps attributable to its inefficiency in the treatment of tabes dorsalis and general paresis, as the accumulated evidence indicates that its value in these manifestations of syphilis is best in the early cases. In the advanced forms of tabes dorsalis or general paresis, the results of treatment of this type are unfavorable.

Patients who have received three or four regular courses of arsphenamine and bismuth or mercury, augmented by several combined intraspinal courses, and whose spinal fluid has not been materially influenced, are those among whom parenchymatous neurosyphilis is prone to develop. Before continuing further with a discussion of methods of treating such patients, I will digress for a brief but fundamental discussion of neurosyphilis. There are three possible explanations

of the development of neurosyphilis: (1) Spirocheta pallida may be of the neurotropic strain; (2) treatment received during the acute phase of the disease may have been insufficient, irregularly given, or even inefficient in its effect, and (3) the "soil" may be predisposed to the development of neurosyphilis, a conception which includes the elusive factors of resistance or immunity. An analysis of these three explanations indicates that although a neurotropic strain of the organism is demonstrable in the laboratory animal, evidence is still lacking that a specific strain with particular affinity for the nervous system attacks man. That inadequate treatment predisposes to neurosyphilis has been demonstrated in this statistical study. An explanation has not been advanced, however, as to why neurosyphilis eventually develops in certain cases even though the patients were treated thoroughly during the early stages of syphilis. It is possible that the treatment, although adequate as to amount and intensity, was inefficient. The third conception involves the factor of lack of resistance, and it seems the most plausible explanation for the failures in treatment. This is evidenced by the frequency with which neurosyphilis develops in the early case in which treatment was adequate. An experience with nonspecific therapy, especially malaria therapy, during the past ten years has repeatedly emphasized the superiority of fever therapy in the treatment of neurosyphilis when the so-called specific remedies have failed. Accordingly, when the patient with asymptomatic neurosyphilis has received arsphenamine and mercury or bismuth in adequate amounts and in an intensive manner, and when intraspinal therapy has been added and tests of the spinal fluid continue to remain positive and to indicate the malignant nature of the condition, it is advisable to adopt a different therapeutic program. When a fair trial with the specific agents fails to produce the desired serologic result in a given case, it is logical to adopt measures that are directed toward stimulation of the patient's resistance and to drop those which have been inadequate in the destruction of the invading organisms. This is the rationale for the use of malaria therapy in neurosyphilitics who have failed to secure serologic reversal.

In several other reports I have called attention to the value of malaria therapy in the prevention of general paresis. When the use of specific remedies fails to influence satisfactorily the course of the disease, application of intensive nonspecific measures will completely reverse the course of the disease in many of the cases. The mechanics by which this is accomplished is still not understood and the method continues to be used empirically. Treatment with typhoid vaccine produces a lower incidence of serologic reversals than malaria therapy, and my experience with electric units that produce fever is still too limited to permit me to pass judgment on their value. Tryparsamide has been proved to be inefficient in the control of asymptomatic neurosyphilis, as the highest incidences of progression to clinical neurosyphilis were noted following its use and the use of silver arsphenamine.

Summary and Conclusions

Asymptomatic neurosyphilis is to be anticipated in approximately a fifth of all cases of syphilis, and it must be eliminated by examination of the spinal fluid in all cases of acute syphilis in which the Wassermann or flocculation tests on the blood remain positive; likewise, if serologic tests on the blood revert to positive when treatment is stopped, invasion of the nervous system should be suspected. Eighteen per cent of patients with latent syphilis who are "Wassermann fast" will be found to have asymptomatic neurosyphilis. The results of treatment in cases of early asymptomatic neurosyphilis are decidedly better than those cases in which the disease is of four years' duration or more. Accordingly, the spinal fluid should be examined early in order that the complication may be handled intelligently. The fact that the patient develops the maximal amount of resistance against invasion of the central nervous system during the first four years should also be kept in mind in treating syphilis of longer duration. Routine measures are successful in the majority of cases, but when they fail the addition of intraspinal therapy may satisfactorily reverse the serologic reaction. The fact that five or more courses of arsphenamine and bismuth or mercury, and intraspinal therapy in addition, fail to produce serologic reversal is indicative not only of a malignant type of involvement of the central nervous system, but also suggests that an adequate defensive mechanism is lacking against such involvement. The use of malaria therapy in such cases apparently supplies the necessary stimulus to the mechanism by which immunity is obtained. Fever therapy is therefore of value in the treatment of parenchymatous neurosyphilis, and in the treatment of asymptomatic neurosyphilis in cases in which satisfactory serologic reversals have not been produced following the use of arsphenamine, bismuth and mercury.

SYPHILIS AS SEEN IN THE NEUMANN CLINIC THIRTY-FIVE YEARS AGO

F. R. Wright, M.D.
Minneapolis

What I have to say tonight is a memory sketch of thirty-five years ago. Incidentally I might say that of the 1,500 men who are practicing medicine in Minneapolis and Saint Paul I do not believe that there are fifty who know syphilis clinically when they see it; their diagnosis depends entirely on whether or not a patient has a positive Wassermann.

I arrived in Vienna in January of 1900. At that time there were two rival clinics, Kaposi Clinic known

as Dermatology and Syphilis, and the Neumann Clinic known as Syphilis and Dermatology. The rivalry between these two goes back quite a little farther. In the early days Hebra, who is known as the father of Dermatology, had two assistants, Cohn and Neumann, both Jewish. He also had a charming daughter. Cohn and Neumann both wanted to marry the girl but Hebra, who was a German, said that he would not have a Jew in his family. A few weeks later Hebra had a heart-to-heart talk with Cohn, who went down to Hungary to the village where he was born and paid one gulden to have his name changed to that of the village, then came back to Vienna and, as assistant, Kaposi married the girl. If any of you are so fortunate as to have a copy of the first edition of Kaposi's Haut Krankheiten you will find at the foot of the first page of the tenth or twelfth chapter a footnote which states "at this point J. Cohn changed his name to Kaposi."

The teaching in those days was purely clinical. The spirochæta and the Wassermann reaction had never been heard of. Teachers at that time believed that each different variety of syphilis was due to a different virus. Professor Neumann taught in 1900 that syphilis was due to a specific cause. He felt that there were three types of this virus: one which attacked the skin, one the bones, and the third the nervous system.

In those days syphilis was not considered as a constitutional disease, it was simply dermatology. We were taught that eruptions developed on the flexor surfaces of the body; that all lesions on the skin were round and painless; all ulcerative lesions were necrotic, not granulating; that the chancre instead of being covered by a granulating surface is covered by necrotic tissue. It is only when the chancre has begun to heal that it presents a granulating surface.

We were taught that syphilis had two incubation periods, one from the time of the infection to the appearance of the initial lesion, twenty-one days; the second period was from that time until the general eruption appears on the body. They traced the age of the infection by the clinical skin condition. If there was a sore on the penis, round with a sloping edge and a necrotic base, it was an initial lesion, infection twenty-one days old. If the base of the sore has become indurated, infection is twenty-eight days. By the thirty-fifth day lymphatic glands on one groin have become enlarged and by the forty-second day, glands of the opposite groin. If the glands in the posterior triangle of the neck and the epitrochlear glands were palpable the condition was forty-nine days old. The eruption came out on the body on the fifty-sixth day. We were taught that the normal course of syphilis, if left untreated, was a relapse every three months. For example, if a man was infected the first of April he would develop an eruption on his body approximately the first of June. This eruption would remain bright for a few weeks and then gradually fade, to disappear partially or completely until about the first of September, when a new eruption would appear. We were taught that the lesions of the new eruption would be the same as those of the primary; that is, a macular eruption would follow a macular eruption and the papular follow a papular. The relapsing eruptions were different from the primary by the fact that they were larger and showed a more or less well-defined tendency to grouping. It was taught that certain eruptions were characteristc of certain ages of the disease, as, for instance, the loss of the hair on the side of the head never occurred before the first relapse, which would be at the fifth month, and was not a part of late syphilis; that the condylomata, or moist papules which develop at points of irritation, as between the buttocks, about the genitals, or under the pendulous breasts of women, never occurred before the ninth month. Every man was taught to know symptoms so that he could tell the age of a given case up to a year.

The teaching was entirely clinical. Professor Neumann lectured from nine to ten o'clock, Professor Kaposi from eleven to twelve o'clock. During the hour from ten to eleven their clinics for ambulatory patients were held. The daily visit in the Neumann wards was made at eight in the morning. I think that I am the only American who was ever invited by Professor Neumann to make the visits with him. I made this morning visit with him for fourteen months. At this visit all patients in the hospital were reviewed. The men came before the Professor wearing a mantle, or linen duster, and a pair of slippers. This mantle was removed, the slippers kicked off. Every patient was examined stark naked although the only lesion on his body might be a spot on his face. If the patient was syphilitic he was required to show the palms and the soles.

In the female wards the girls wore a loose blouse, short skirt and slippers. When they came up before the Professor the blouse was removed, they then dropped their slippers and were then put up on the table. The skirt was pulled up and the lower half of the body and genitals examined.

The treatment of syphilis at that time was entirely by mercury. The Kaposi Clinic used hypodermic solutions of salicylate, bichloride or succinamide of mercury. The Neumann Clinic used the inunctions of mercurial ointment exclusively. Both clinics agreed that it was a mistake to begin treatment in a case of syphilis before the constitutional symptoms had appeared; that no matter how early it was begun it would not prevent, simply delay, the appearance of the eruption. They were also sure that the cases treated early, that is, before the eruption appeared, did not run a normal course. In the Kaposi Clinic the hypodermics were given intramuscularly in the gluteal region, the soluble salts given every day and the insoluble salicylate given once a week. In the Neumann Clinic the inunctions were carried out by the patients themselves. Six men were placed astride a narrow bench, each rubbed the mercurial ointment into the back of the man in front of him. Every day the man in the front of the row took his place at the foot so that in a week each man had six days' treatment and one day's rest. As

a routine, the course of treatment inunction was kept up until all symptoms disappeared and then continued half again as long. The average course was about six weeks, and under no circumstances continued longer than eight weeks whether symptoms had disappeared or not. It had been clinically observed that at the end of eight weeks patients became satiated with mercury and the treatment was no longer effective. Following this routine course of treatment a patient got four courses of mercury the first year, the second year he was given three courses, in the third year one or two depending on the number of clinical relapses he had developed. After that no further treatment was given. If at the end of the fourth year the patient had been without clinical symptoms for a year he was considered cured and was allowed to marry.

Syphilis was known to them as a disease of the skin. They believed and taught that nerve syphilis, which they called parasyphilis, was not due to the syphilis virus but to the toxin which had been produced and had remained in the body.

At my last visit to Vienna in 1906 the spirochæta had been discovered and I saw in the laboratory of Professor Ehrmann the first spirochæta that was ever stained in nerve tissue. Some years later Noguchi stained the spirochæta in the spinal cord, proving that locomotor ataxia is due to a direct invasion of the cord by the parasite.

Discussion

Dr. C. D. Freeman, St. Paul: Syphilis has been discussed this evening from A to Z. As you have probably noticed, there have been no recent advances in its treatment. The real messages as regards syphilis are all history and some of them have been very important. Whether any new discoveries are to be made remains to be seen.

Off-hand, I would say there have been about six messages pertaining to syphilis that stand out prominently:

1. Discovery of causative factor.
2. Ehrlich's salvarsan therapy.
3. The Wassermann blood test.
4. Noguchi's finding of the spirocheta pallida in the brain and cord tissue.
5. Malarial inoculation for paresis.
6. Bismuth and tryparsamide therapy.

Twenty-five years ago, or before Schaudin and Hoffman discovered the spirocheta pallida as the causative factor of syphilis, we were taught not to treat the primary lesion of syphilis until the secondaries appeared, with the result that the patient carried an infectious lesion for six weeks, and then, when the secondaries appeared with mucous patches, etc., he became doubly infectious; and this was followed by several weeks more of transmission until the patient was under control with mercurial rubs or salicylate of mercury injections. It is easy to understand how difficult it was to control a disease under these circumstances.

At present, when a patient with a primary lesion presents himself, a dark-field examination is made and he is given a salvarsan at once. Twenty-four to forty-eight hours after his first salvarsan injection it is difficult to find any organisms in the lesion; and, personally, I believe after the second or third salvarsan he is not infectious and will remain so providing he continues his treatment.

As to the Wassermann reaction, it has been a great aid when there is any doubt as to diagnosis. In every general examination by any medical man, a Wassermann test should always be included. In this way, cases of syphilis are picked up which would otherwise be overlooked. A four plus Wassermann reaction does not by any means prove conclusively that a patient is infectious, but it indicates that treatment should be given, especially to ward off late visceral manifestations.

Noguchi's discovery of the spirocheta pallida in the brain and cord tissue put general paralysis and locomotor ataxia 100 per cent in the syphilis category. Malarial treatment for paresis, while not 100 per cent perfect in any sense, offered us a method in treating a previously fatal condition, and in which we now obtain in some cases very good results.

Bismuth and tryparsamide have also been adjuncts in our therapy.

The above methods have reduced syphilis to a minimum, especially in Minnesota, which is the only region I personally know about. In my office, a primary lesion is a rarity; and, in talking with other dermatologists, their experience seems about the same. At the Ancker Hospital in St. Paul, there have been two primary lesions in the out-patient department in the last six months; and at the University Hospital there have been about ten during the last year.

Wassermann tests on 5,000 University students gave five positives, three of which were congenital, one extragenital, and only one contracted by sexual intercourse. Dr. Cole told me that, at the Shriners' Hospital for Crippled Children, a positive Wassermann is a rare occurrence. And I received the same report from Dr. Hedenstrom at the Baby Welfare Clinic in St. Paul.

Syphilis is, and always has been, a social problem; but it is definitely under control and is disappearing rapidly; this, in my opinion, is due to the above discoveries which I have mentioned, and not by "educating the public," which, to me, is more or less of a myth pertaining to things medical.

Dr. Gordon Kamman, St. Paul: I was glad to hear Dr. O'Leary say that, in the treatment of neurosyphilis, he feels that malaria is more effective than any other forms of pyrotherapy. Walter Freeman, of St. Elizabeth's in Washington, D. C., has shown that malaria produces a reaction in the reticulo-endothelial system that does not appear in other forms of fever therapy. I suspect that the participation of the reticulo-endothelial system has something to do with the resorption of the perivascular exudates that we see in neurosyphilis. In Von Jauregg's Clinic in Vienna, I recall seeing sections in which the actual passage was shown of perivascular exudates through the walls of the capillaries. This connotes a change in the permeability of the endothelium that is produced by the dynamic action of the malarial parasite. This action cannot be produced by the various other methods of artificial fever production. Malaria seems to be the only agent that causes this type of reaction. This undoubtedly has a bearing on the relative merits of malarial therapy and other forms of fever therapy. I think statistical studies tend to show that malarial treatment produces a higher percentage of remissions than other forms of fever therapy.

I would like to ask Dr. O'Leary whether or not insufficient early treatment is worse than no treatment, or whether insufficient early treatment really does help.

Dr. F. R. Wright, Minneapolis: Regarding the treatment of late syphilis, it is not the temperature at all which does the work. It so happens that in malaria an immunizing agent is produced which, at certain stages, produces a positive Wassermann. Instead of the temperature, it is the theory that malaria produces some immunizing body which kills the spirocheta.

Dr. S. E. Sweitzer, Minneapolis: In general we find that the neurologists feel that these patients who have no active symptoms should not be actively treated. But I feel that we should treat the so-called preparetics with malaria and intensive post-malarial treatment with arsenic and bismuth so that they will not get paresis. The figures which Dr. O'Leary has given us tonight show that very well.

Dr. H. L. Ulrich, Minneapolis: The only vector for syphilis is the human body. We cannot kill the vector, so we must destroy the treponema pallidum. The acceleration of this destruction lies in the improvement of our arsenicals. My criticism of the specialists is due to the fact that in the last thirty years they have fallen down. The only benefit I can see in a campaign is not one of education but one of propaganda which would emphasize the early treatment of syphilis.

Dr. Paul O'Leary, Rochester: The people of Minnesota are indeed fortunate in having had, back in 1921, two men interested enough and with sufficient vision to have created a venereal disease program that has become a model for this country. I refer, of course, to Dr. H. G. Irvine and Dr. A. J. Chesley of the State Board of Health. Even when the funds which were originally set aside by the state legislature were discontinued, Dr. Chesley and Dr. Irvine were able to carry on a campaign that has maintained a state serologic laboratory of the highest type, that has supplied drugs to physicians for the treatment of indigent patients with gonorrhea and syphilis, and that has maintained a consultation service for the physicians of the community. The adoption of the Minnesota plan by the national health officers as a model type of program should indeed be a source of satisfaction and encouragement to these two pioneers in the venereal disease campaign.

In answer to Dr. Kamman's question, I believe very decidedly that the modern treatment of syphilis does not produce neurosyphilis but rather that it actually prevents its development. The basis for this assertion is that, of a group of 500 patients with clinical neurosyphilis, 72 per cent had not been treated for syphilis when the neurologic disease was recognized. Of those who received treatment, even though it was insufficient in amount according to our present-day standards, only 8 per cent developed clinical neurosyphilis. Likewise, when we studied those patients who were given the recommended amount of treatment, only 4 per cent showed either invasion or involvement of the central nervous system. The statistical evidence is decidedly in favor of the modern treatment of syphilis as the best "preventer" of neurosyphilis we now have at our disposal.

The successful serologic and clinical results that follow malarial therapy are apparently not due to any symbiotic reaction between the plasmodium vivax and the spirocheta pallida, as Dr. Wright mentioned. The reason for this is that other types of organism, spirochetal and bacterial, as well as the by-products of these organisms, have produced equally satisfactory results in the patient with syphilis; but there use has not become popular because of controllable complications or the inability to control the disease produced.

Dr. F. R. Wright: Answering Dr. O'Leary, I might say that the spirocheta does not live in the blood stream; it lives in the tissue fluids. Fever alters the character of these fluids. That is what happens when you treat gonorrhea with heat. Forty years ago they taught at the clinic in Vienna that only 2 per cent of the cases treated by mercury for over three years would develop neurosyphilis; so, if the figures Dr. O'Leary just gave are correct, and these old figures in Vienna are correct, from a neurological standpoint the end-results have not improved much in the treatment of syphilis.

The meeting adjourned.

Albert G. Schulze, M.D.,
Secretary.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

MENTAL THERAPY. Studies in Fifty Cases. Louis S. London, M.D., formerly Assistant Surgeon (R) United States Public Health Service; Medical Officer United States Veterans Bureau; Assistant Physician, Central Islip State Hospital, Central Islip, New York. and Manhattan State Hospital, Ward's Island, New York. Cloth. Price, $12.50. Two volumes, pp. 774, with 22 diagrams. New York: Covici, Friede, 1937.

These two volumes present fifty case histories of various types of neuroses and psychoses. The larger part of this work is taken up with cases of sexual neuroses. The author is a student of Freud's school of psychoanalysis and uses Freud's interpretation in his analyses. Is is very questionable that this work will, as the publishers aver, displace Krafft-Ebing's "Psychopathia Sexualis," mainly because only a comparatively few types of sexual perversion are discussed. The title, "Mental Therapy," is misleading for a large proportion of the case histories have no mention of therapy. A more accurate title would be "A Freudian Interpretation of Fifty Cases of Neurosis, Sexual Perversion and Psychoses, with Emphasis on Sexual Perversion." For those who cannot stomach psychoanalysis this contribution is not recommended. For those who do believe in psychoanalysis it offers nothing essentially new.

N. J. Berkwitz, M.D.

MANUAL OF DISEASES OF THE EYE. Charles H. May, M.D. 498 pages. Illus. Price $4.00. William Wood and Company, 1937.

This work first published in 1900 has now gone through fifteen editions and while it contains almost 500 pages it is still of convenient size.

For the undergradute and general practitioner it is perhaps the most ideal work of its kind. Diagnosis and treatment have been brought up to date; selected operations for the respective fields have been well chosen, clearly described and illustrated; and the colored plates are especially illuminating although former editions had similiar plates

That the work has great merit is evident by the fact that it has been translated and printed in several editions in eight foreign tongues.

George C. Dittman, M.D.

PROCEEDINGS of the MINNEAPOLIS SURGICAL SOCIETY

Stated Meeting, Thursday, January 6, 1938

President, Dr. O. W. Yoerg, in the Chair

THE USE OF FASCIAL TRANSPLANTS IN HERNIOPLASTY*

Stanley R. Maxeiner, M.D., F.A.C.S.

Erdman, in a follow-up of 978 herniotomies on patients over sixty years of age, found 10 per cent recurrences after operations for oblique hernias and 42 per cent recurrences after operations for direct hernias. The regular gut suture method of hernioplasty is followed by 15-25 per cent recurrences in direct hernia and 40-50 per cent failures after operation for recurrent hernias. This is not due to faulty technic when all the surgical indications have been complied with, namely, removal of the sac, proper approximation of tissues, primary healing, and an adequate healing period.

Reoperation reveals that the tissues have not remained as they were approximated surgically, but have separated and returned to their original position with the formation of a new sac. The answer must be found in the deficiency of the healing process.

Healing takes place first by the advent of inflammation followed by new fiber cells and blood vessels resembling granulations which eventually become scar. Two edges of fascia sutured together become united by scar whether approximated edge to edge or overlapped. Union of fascia to muscle takes place by the formation of new scar joining the fascia to the fibrous covering of the muscle bundles. It naturally implies, therefore, that approximation must be maintained until adequate scar is formed to insure against stretching and separation under stress. Absorbable sutures often fail to accomplish this objective. Non-absorbable sutures, on the other hand, if they do not cut out under tension are found to be incorporated in a strong bed of scar. Experimentally, Mootz, Selig and others found that removal of intervening areolar tissue and scarification of approximated surfaces aids the security of the healing process.

Gallie in 1921 reported his work, experimental and clinical, on the use of living fascial sutures and grafts. Free grafts were found to shrink and became joined to hernial rings by wide areas of scar tissue. This was overcome by the use of grafts resembling the many tail binder, the tails being sewed into the surrounding tissues. Fascial strips cut from fascia lata and used as sutures were found to be stronger than catgut or kangaroo tendon and were less irritating to the tissues, producing little or no reaction. They became incorporated in the healing scar and were demonstrated two to five years later as persistent fibrous cords of equal tensile strength and unshrunk as demonstrated by spacing silk markers along the sutures. McArthur in 1901 described the use of a fascial suture procured from the medial cut edge of the external oblique and left attached at the pubes. We used his method successfully in the early days of my association with Dr. Farr but it was later only seldom employed. Recently, however, popularity seems to have returned it to its just place in surgery. Our own experience based on 383 hernias repaired by the McArthur fascial suture has reduced our recurrences three and a half times when used in the repair of direct hernia. We have reserved the McArthur operation for the milder type of direct hernia, some selected recurrent hernias, and certain indirect hernias in older persons.

The Gallie operation is more radical and has been reserved for post-operative incisional hernias where the edges can not be brought together without too much tension or where a gap actually remains between the edges. This gap is darned with fascial strips as one might mend a sock. We have recently repaired all recurrent inguinal hernias by this method. Large umbilical hernias, selected femoral and epigastric hernias and certain large long-standing indirect hernias where tissues are weak lend themselves best to the Gallie method of closure.

Gallie in 100 herniotomies, most of which were for direct or recurrent hernias, had no recurrences although three wounds suppurated. Burdick in 163 cases, twenty-nine of which were for recurrence, had four recurrences only. Behrend performed 125 operations with three recurrences and recommends the use of fascial sutures in practically all herniotomies. Burdick, Gillespie and Higinbothan (Am. Surg., 1937) report the only adverse criticism found in the literature reviewed by the writer. However, they report 133 infected wounds in 1,485 cases, 7.9 per cent of the wounds with autogenous sutures and 12 per cent with ox fascia being infected. Of 975 followed operations of all types of hernia 284 failures occurred. They report 15.4 per cent recurrences in indirect hernias with the use of fascia and now employ silk sutures almost exclusively. These statistics are not as good as those obtained by the use of catgut and their percentage of infections is very high.

In discussing sutures Koontz remarks as follows:

A. (1) Catgut is uncertain as to its duration and may disappear before the healing process is complete; (2) in the presence of collected serum it softens and often unties; (3) unfavorable reaction to the tissues about the sutures is common.

B. Silk is not absorbed and is more dependable and there is very little reaction in the surrounding tissues.

*From the Department of Surgery, University of Minnesota.

The objection to silk is based on the grounds that it is a foreign body and often leaves a sinus or it may cut through.

C. Animal fascia preserved in alcohol (70 per cent) still has collagen fibers undestroyed and live cells penetrate and incorporate the sutures as in a graft of autogenous fascia.

Autogenous fascial sutures do not absorb but continue to function for all time. They are strong and easily procured. Fascia may be used as a graft, pedunculated flap or as a suture. Fascial sutures may be mounted on a Gallie needle or may be pulled through by small forceps which penetrate the layers to be united. The strip should be anchored at regular intervals, preferably with silk, as fascia is very slippery. Defects may be darned by strips or the layers may be brought together by the ordinary running suture if there is no undue tension.

Personal cases from our own private practice consist of twenty-eight hernias repaired by fascia; fourteen by the McArthur method and fourteen by the Gallie technic.

At the Veterans Hospital at Ft. Snelling, Dr. Sedgeley, Dr. Culligan and I have performed 405 herniotomies by using fascial transplants. There have been 372 operations of the McArthur type and thirty-three operations of the Gallie type.

Among the writer's twenty-eight patients there has been one infected wound with prompt failure. This was a strangulated hernia recurrent seven times in which we ill-advisedly attempted to do a Gallie suture to obtain permanent relief. The infection in this instance was unquestionably due to the presence of bacteria from the incarcerated bowel. None of the other twenty-seven cases became infected and there have been no recurrences to date.

In order to completely clarify my stand on the use of fascia I would state that I am not recommending the use of fascia for the ordinary indirect hernia, especially in young people, where even the removal of the sac alone may be adequate, but I am advocating its use as stated in the text and in the report of the following cases where, in my judgment, catgut closure is apt to be followed by failure. Occasionally one hears the statement that removal of fascia lata strips from the thigh may be followed by muscle hernia. We have not experienced this condition as yet in forty-seven cases in which we have removed strips of fascia lata. Following the rendering of the above paper, ten cases treated by the Gallie and McArthur operations were personally shown as a clinic. Six of the most interesting ones are herewith reported.

Case 1.—Mr. F., aged sixty-five, has had two herniotomies on the left side in 1911 and 1919 and one herniotomy on the right side in 1919, all of which recurred. The patient has been treated by hernia injections on both sides for a nine-month period without improvement. In August, 1936, the right (which is giving the most symptoms) twice-recurrent hernia was repaired by the Gallie technic using three strips of fascia lata one-fourth to one-third inch wide. One and a half years later the closure is entirely satisfactory. The left side has not been operated upon because the patient has subsequently had an attack of coronary thrombosis. Nevertheless he has returned to his regular occupation as stationary engineer.

Case 2.—The patient, male, aged fifty-four, was operated upon for a ruptured appendix with drainage thirty-seven years ago. This operation was followed promptly by a large ventral hernia. The ventral hernia was repaired twelve years ago by the catgut method but again recurred one year later. He was treated by eight injections in 1935 without relief. He had been treated for angina pectoris for the preceding two years and suffered severe pain on exertion. He complained bitterly of pain and symptoms of partial obstruction. The hernia was about the size of a large grapefruit medial to the right anterior superior spine, was irreducible and painful. In June, 1936, under local anesthesia a plastic repair of the ventral hernia was performed. A large double hernia in the right groin and loin was found at the time of the operation. It was impossible to reduce the hernia without opening the sac and separating the adherent loops of bowel. The fascia layers were carefully dissected out and were grossly inadequate to assure a competent closure. Three wide strips of fascia lata were woven into the defect after bringing the layers together with catgut. The patient complained of anginal pain during the operation and required supportive treatment. It is now nineteen months since this operation without recurrence and the scar is entirely competent.

Case 3.—Mrs. C., female, aged forty-four, was operated upon seven years ago for cholecystectomy. Five years ago she developed an incisional hernia which has increased to tremendous proportions. The hernia was larger than a cocoanut and was producing symptoms of partial obstruction. At operation January, 1934, the old scar was excised, the bowel loops freed and reduced, the fascial layers freed and separated and a plastic repair of the hernia was completed using three wide strips of fascia lata. It is now more than four years since this hernioplasty and there is no recurrence and the wound is entirely competent.

Case 4.—Mr. K., aged forty-three, had a history of recurrent bilateral inguinal hernias. The patient was operated upon one year previously for bilateral hernias both of which recurred within three months. Following the recurrence the patient was treated with many injections without result. Operation: bilateral plastic herniorrhaphy after the manner of Gallie using three strips of fascia lata on each side. The primary repairs were both performed at the same time while two weeks intervened between the right and the left secondary repairs. It has been our custom not to do two hernias at one time as it is our opinion that much better results can be obtained by performing them at intervals of at least two weeks.

Case 5.—Mr. L. A. J., aged thirty-eight, came to us with a hernia three times recurrent on the right side and two times recurrent on the left side. Both sides were repaired by the Gallie technic in January, 1933. It is now more than five years without recurrence. His occupation demands more than usual heavy exertion.

Case 6.—This is one of the most outstanding cases it has been my privilege to encounter inasmuch as the patient has had nine recurrences following operation for repair of the inguinal defect. Mr. M., aged forty-four, suffered a gun-shot wound of the right inguinal region in France in 1918. An operation was performed in an attempt to remove a machine gun bullet through the inguinal region without success. A second operation was performed removing the bullet

by approaching it from the rear of the right thigh. The inguinal wound suppurated and necessitated removal of slough and fragments of bone. A hernia subsequently developed from which the patient has been operated upon subsequently nine times. At the last preceding operation the surgeon ingeniously withdrew the testicle from the scrotum, passed it behind the right rectus muscle, out the midline and back again into the scrotum and then closed the inguinal canal. This was followed not only by hernia in the inguinal region but likewise one in the midline where the cord emerged from behind the rectus. In October, 1937, the patient agreed that we might remove the testicle or resect the cord if we thought it would give him a better chance of a permanent cure. Operation: a long oblique incision was carried downward over the inguinal canal into the midline over the pubis. The cord was exposed in the inguinal canal following beneath the rectus muscle and to the scrotum as described. Under the circumstances we reasoned that the testicle having been delivered from the scrotum must have developed a new collateral circulation from adhesions to the surrounding tissue. For that reason the testicle was not removed but the cord was doubly ligated and completely excised to the peritoneum. The midline hernia, the rectus sheath, and the inguinal canal were now closed tightly, using three, more than ordinarily wide fascial strips. The layers were imbricated and deep bites were taken into the normal tissue on both sides of the approximated tissues. It is now only four months since the last repair which was done by the Gallie fascial strip technic and it is altogether too early to report the result of this operation. However, we believe that we have given this patient his best chance for a permanent cure. It is interesting to note that there was no swelling of the testicle following the division of the entire cord and it remains the same size as the testicle on the opposite side.

Motion pictures in color of fascial operations performed by both Drs. Culligan and Maxeiner were shown demonstrating the technic of the two types of fascial strip operations.

Discussion

Dr. Leo Culligan: In 1931 when we first started using fascia in the repair of hernia at the Veterans' Hospital, we limited its use to large ventral hernias, the larger recurrent hernias, and those recurrent hernias which had come back more than once. For that reason, during the next three years, we used it in only nine cases, all by the Gallie technic. In February, 1934, we became interested in the old McArthur operation originated by him in 1901. The use of this simple and effective means has so widened the scope of the use of fascia that up to the present time we have used it in 406 cases, thirty-three of these by the Gallie technic, and the remainder by the McArthur technic.

From the experimental work of many men we know that fascia as a suture material persists and does not absorb. Some men say that it continues to live much like transplanted skin lives. Others say that it persists as an inert tendinous structure which becomes infiltrated from the surrounding tissues. However, all agree that it is not absorbed, and that it will continue to hold tissues together in place where one sutures them.

From our own experience at the Veterans' Hospital we know that fascia is an innocuous kind of suture material. The wounds in which it is used heal readily without irritation and without any undue formation of serum. We have had a low incidence of infection, somewhat higher percentage in the Gallie than in the McArthur operation, yet the series using the Gallie technic is so much smaller that the comparison is hardly accurate. In the Gallie we have had four infections in thirty-three cases (12 per cent), while in the McArthur herniotomies done during the last year, amounting to 132 operations, we have had only two infections (1.5 per cent). In all our cases, even those which have become infected, we have never had a fascial strip slough. A year ago in a paper before this society I compared the results of the use of catgut and fascia in the repair of the direct hernia. At that time I showed that we had approximately three and one-half times the recurrence rate using catgut that we had had using fascia.

In view of this satisfactory experience I now use fascia almost as a routine in the direct hernia, the large indirect hernias, sliding hernias, the ventral hernias, and the recurrent hernias. Whenever possible I use the McArthur technic.

Because I prefer this simpler McArthur technic in repairing the recurrent inguinal hernia I do not use the suggestion of Gallie to take the fascial strips from the thigh before opening the herniotomy wound, for I have found that in the majority of these cases one can get sufficient fascia locally to make a satisfactory repair. Possibly it is just that I have a weakness for the method of McArthur. However, it has been my experience that in most recurrent inguinal hernias the defect is a small one, often not larger than two or three centimeters in diameter, and for that reason one does not need a great deal of fascia to make a good repair. Moreover, the repair of the recurrent hernia using fascia, can be different from that using catgut in that it is not necessary to break down the floor of the canal in order to get sufficient tissue to overlap and make our closure in that way. All we have to do is to pull the edges of the defect together with fascia and they will hold where we put them.

So in repairing the recurrent inguinal hernia, after dissecting out the defect, I have been taking a strip of fascia from the adjacent aponeurosis of the external oblique, leaving it attached near the fascial defect and using it is suture material. I have been able to use this method in the last thirty-two consecutive recurrent inguinal hernias upon which I have operated and as yet none of them have returned for reoperation. On the other hand when the defect is large, and I cannot get sufficient fascia locally to make the repair, I go to the thigh and take enough fascia to make a firm closure.

On the whole, our experience with fascia has been so satisfactory that now whenever I operate any hernia, especially in a patient over the age of thirty-five or forty, I ask myself the question, "Why not use fascia?" As time goes on it is becoming increasingly difficult to find sufficiently good reasons for not using it.

Dr. Frank R. Sedgley (by invitation): This would be a wonderful opportunity to review the history of the surgical treatment of hernia from prehistoric times, but I will refrain owing to the length of the program this evening. Until the advent of modern surgery no real progress was made in the treatment or the understanding of hernia. The subject remained in the same status as during the Dark Ages.

There were three factors that changed the situation. These were the principles of antisepsis and asepsis, improved surgical suture material and a better understanding of the anatomical relations to the lines of intra-abdominal force, intra-abdominal pressure and especially the stresses that occur upon the operated structures. The Bassini and Halstead operations, as well as a score of others that bear proper names, reflect the progress of development of a better anatomical understanding.

The first two factors preceded and were necessary to the development and application of the anatomical principle in the same degree that they were and still are fundamental to the development and progress of

modern surgery. Asepsis is an absolute term and implies, naturally, a perfection in that particular direction, but it is a perfection that is practically obtainable. Surgical sutures nowadays are excellent and for wide general uses are near to perfection but in the special field of hernial surgery with its transposed anatomy, the three factors do not combine as effectively as in many other circumstances. The use of living, autoplastic fascia, I believe, represents, if not perfection, at least a distinct improvement in the suture factor. It may be thought of as bearing the same relation to other sutures as vital staining of the blood and other tissues does to ordinary staining methods. Whether there is anything essentially vital in it or not, one warning should be borne in mind: the fascial strip, whether free or pedicled, remains a suture still and as such must be carefully applied. It has such a smoothly sliding, sleek quality that it must be firmly anchored in its position at several points to insure its fixation and later incorporation where desired. This is done with accessory sutures of plain and chromic gut, or silk as may be preferred.

I want to express my appreciation of Dr. Culligan's laborious and painstaking efforts in going over our large number of cases at the Veterans' Hospital and I anticipate that his analysis of our present practice continued over a longer period will show a definite improvement in our own recurrence rate, and especially in results of operative procedures on recurrent hernias.

Dr. Willard D. White: In these cases that have to be operated on for bilateral hernias, do you do them both in the same sitting or do you do one and allow it to heal and then do the other side?

I would also like to add that Dr. MacArthur had described this operation in 1901 and then somewhere around 1904 he showed, at a meeting, a patient who had been operated upon in 1901 with this McArthur operation of fascial suture. Then, this patient died from some other cause somewhere about 1904 and he had the specimen removed at autopsy and it showed that the fascial strips that had been placed in the wound nearly four years previously still remained* and you could trace the course of these strips, showing that the strips do actually live.

Dr. Hamlin Mattson: There is still another possible use for fascia transplants which I tried recently. A primipara, aged thirty-two, suffered a third degree laceration following breech delivery August 21, 1934. Two extensive procedures performed elsewhere had failed. The patient had complete fecal incontinence and absence of the rectovaginal septum for a distance of 6 cm. proximal to the anal sphincter. The tissues showed extensive scarification. On April 22, 1935, the rectum was freed and drawn downward and the remnants of the levator ani muscles sutured. The wound healed well with the exception of the ends of the sphincter, which did not unite. On May 7, 1937, the ends of the anal sphincter were freed and sutured with three strips from the fascia lata. Apparently fascia transplants when buried in poorly vascularized scar tissue are transformed into scar and when in better vascularized tissues remain in as fascia indefinitely. Nevertheless, this patient obtained complete functional control of her bowels.

Dr. R. Hultkrans: Dr. Dunn had a case when I was with him. A man of considerable weight fell and ruptured both quadriceps tendons. They were completely ruptured because he had no power of extension at either knee. Repair was done with fascia lata. Dr. Dunn is here and can probably tell us about it.

*This statement was made in a discussion, by Dr. E. S. Murphy, of a paper on fascial sutures in the repair of inguinal hernia by W. J. Pickett, Illinois Medical Journal—Vol. 59, p. 227, March, 1931.

Dr. George R. Dunn: This was a rather heavy chap and he evulsed the quadriceps tendon at the top of each patella. We used fascia lata in restoring them. He got practically a perfect result on one side and a fairly good result on the other side. He weighed, after considerable reducing, about 265 pounds. The use of the fascia was about the only way we had of restoring the continuity of the tendons. There was no fracture, simply an evulsion of both quadriceps tendons from the patella on the right and left sides.

Dr. Stanley R. Maxeiner: With reference to Dr. White's question, I personally have not done a double hernia at one sitting for several years. The man who had a bilateral hernia had a three weeks interval between the two operations. I personally think it is wise to have an interval of probably two to four weeks as the closure of the two hernias undoubtedly exerts additional tension on both lines of sutures and one or both are more likely to give way.

With reference to Dr. Mattson's remarks, I wish to add that they are using fascial strips for almost everything and they have been repeatedly using them in the repair of extensive laceration of the perineum where the tissue is inadequate. At the last meeting of the Western Surgical Association, Dr. Charles Mayo, Jr., showed motion pictures of a new technic in which he used fascia lata for building up the pelvic floor to cure prolapse of the rectum. The exposure is through an incision similar to that used in operation for carcinoma of the rectum. The peritoneum is opened and the rectum and sigmoid is tucked up into the abdomen. Fascial strips are then woven in such a manner that a new internal pelvic floor is made which fits around the rectum. They had a very successful result in the one case which he reported.

FEMORO-ILIAC THROMBOSIS AND THROMBOPHLEBITIS

H. O. McPheeters, M.D.

Much has been written on the subject of thrombosis and thrombophlebitis. The importance of its prophylaxis, care at the time of onset and the treatment of the sequelæ that may often follow, has not yet received proper attention. This is well borne out by the splendid presentations the past year. The paper by Homans[1] is a most complete thesis on the subject, while Edwards[3] has given evidence as to the destruction of the venous valves in severe cases.

Pathologists and clinicians agree that the first and most important factor in the development of a thrombophlebitis is a slowing of the blood stream. An injury to the intima of the vessel, either traumatic or infectious, furnishes a focus for its development. Blood platelets are then deposited at that area in the slowly moving blood stream. Thrombocytes appear and then fibrin is deposited which enmeshes the blood cells. The process may terminate with only a slight local involvement or it may close the vein lumen and extend in both directions. The extension of the process terminates at the inflowing of collateral veins with a good current. It is the thrombus attached to only a portion of the vein wall and only partially filling the vein lumen that is provocative of most of the emboli. There may be sufficient current present at times to

carry a portion of the poorly attached thrombus, which may become loosened by exercise, in a proximal direction.

The infection is hematogenous, and may arise from some distant focus, or may be by way of the lymphatics. In the latter case it is thought to be carried in the perivenous lymphatics and then to involve the vein wall from the outside by direct extension. It then penetrates the wall and causes an inflammation of the intima to initiate the thrombophlebitis. Barker[2] has discussed primary idiopathic thrombophlebitis and cites cases in which no probable source of the infection was ever found.

Homans[3] has divided thrombophlebitis of the lower extremity as follows: deep femoro-iliac thrombophlebitis commonly called "phlegmasia alba dolens"; deep peripheral thrombophlebitis involving the deep cavernous viens of the calf; thrombophlebitis of varicose veins; thrombophlegitis of non-varicose veins.

At this time I wish to discuss only the deep femoro-iliac thrombosis and phlebitis and present three case reports of patients who, I believe, had this condition. In each case the symptoms were so acute and severe as to leave no doubt but that the pathology was initiated in the femoro-iliac segment of the vein. The onset of the condition in each case was rapid and the symptoms of thrombosis were more prominent than those of phlebitis. The condition is most dramatic for both the doctor and the patient. In one case the onset and pain was similar to that of an arterial embolus.

Case 1.—Mrs. T., aged forty-eight, a housewife in good general health, three years previously had stumbled on the steps and bruised her left knee and leg over its outer and middle surface. Following this she recovered with bed rest. One year later and more than a year before I saw her, she complained much of a pain along the crest of the left tibia and the outer middle third of her left leg. There was also a sharp pain at times in the left mid-thigh. This was along the distribution of the left femoro-cutaneous nerve. Both she and her home physician associated both these pains with the fall of three years previously and with some small varicose veins that had developed since.

Careful examination showed the patient in good general health and with no complaints other than the above described pains and the few varicose veins. I advised both her doctor and the patient that I did not think the varicose veins were the cause of the pains but suggested that we inject them to rule them out. The varicose veins were injected with sodium morruhate 5 per cent with good results and the usual local reaction. The original pains still persisted.

Five days after the injections the reaction was rapidly subsiding. The patient was sitting waiting for her husband planning to return home when she felt a pain in the left groin which rapidly became worse. Following this she said the entire leg seemed to feel "full." She came to my office at once, a distance of two blocks, crying with pain. The pain was principally in the groin and upper thigh but also somewhat throughout the entire leg.

Examination showed the entire left leg very cyanotic and swollen. The skin was tense. The cyanosis showed a sharp line of demarcation at the groin which passed outward even with the greater trochanter. It was not more than 3 inches from the normal pink skin above to the deeply cyanotic skin below. The pulsation in the femoral and popliteal arteries was good. The foot was too badly swollen to permit palpation of the dorsalis pedis. The temperature was normal.

The patient was sent to the hospital. The leg was put in high elevation and hot magnesium sulphate packs were applied. Four hours after onset the temperature was 99; at the end of the twenty-four hours 99.4; and at the end of forty-eight hours it was 100.4. It rose to 100 daily for four days and then dropped to 99 for the rest of her stay in the hospital.

During her stay in the hospital the hot packs were removed for 1 hour at a time twice a day and the electric baker was applied over the entire leg.

There was no medication given directly for the condition itself as I did not think the patient had a true infectious phlebitis. The patient had a great deal of pain and she was kept under sedatives all the time.

She went home by ambulance on the eleventh day and continued the hot wet packs four hours twice a day followed by the electric baker. She continued this treatment for eight weeks. The pain through the entire leg gradually lessened but the original pain in the external thigh and lower leg continued. The leg was painful when held dependent but the patient was urged to be up and about with an Ace bandage on the lower leg. This gave her much relief.

Six months after the onset of her complication she returned and Dr. R. P. Caron injected the painful areas with novocaine and later with quinine and urea hydrochloride 1—600. This was repeated one month later. Today the patient has recovered almost completely. She has no pain but does wear an elastic stocking which easily controls the swelling.

In this case the thrombosis must have been either the result of an idiopathic phlebitis, as suggested by Barker, or the delayed result of the injections, a condition such as I have never seen before, even though the reaction from the injections was only the usual amount and that was rapidly subsiding.

Case 2.—Mrs. W., a housewife, aged forty-four, had an attack of influenza in February, 1937, and was bedfast for three weeks. In bed, while convalescing, she suddenly developed severe pains through the left inguinal region and throughout the entire left leg. Four hours later, by daylight, she noticed that the entire left thigh and lower leg was of a greenish, cyanotic color. Both pain and cyanosis were aggravated on standing. The patient did not have a chill and the doctor said her temperature was normal.

She was sent to the hospital for five weeks, where two blood cultures were negative. There was only a moderate swelling of the leg during that time, while in bed, but it did swell and the pain was worse as soon as she would get up and about.

After another four weeks in bed at home she began to get up and about with an Ace bandage on the lower leg. Without it the lower leg to the knee would become dark, cyanotic and swollen.

The attending physician at that time diagnosed the condition as a femoro-iliac thrombosis and not a thrombophlebitis.

The patient was first seen by me on September 1, 1937, at my office. The entire left leg, from the groin to the toes, was larger by actual measurement than the right leg. The skin was definitely cyanotic in relation to that of the right leg and the abdomen. The patient was wearing an Ace bandage on the lower leg. When this was removed there was but slight edema and the color was good. The femoral, popliteal and dorsalis pedis arteries were normal. The left great saphenous vein was palpable and only half an inch in size, not at all large enough to be considered a compensatory vein. Tests proved it was not. After the

bandage was removed the leg became discolored and there seemed to be a definite line of demarcation of the cyanosis about the level of the knee. After a forced walk of four hours without the bandage the swelling was only moderately increased and the color was good. The leg rapidly became cyanosed on standing. I advised her to continue wearing a Lastex stocking and go about her work.

On November 18, 1937, the patient reported that she had led a normal life, including dancing, and felt fine. She was not handicapped by the leg. There was still some cyanosis and swelling of the lower leg to the lower thigh when going without the supportive stocking.

Case 3.—Mr. S., aged fifty, a millwright, had an injury to the left ankle and foot many years previously. Two years before the present illness I treated him for a bad varicose ulcer and injected a large group of varicose veins. The patient was last seen one year previously. On December 30, 1936, he presented himself at the office with the history of having had the varicose ulcer recur two weeks previously but stated that it was rapidly getting worse. He also had had a severe pain develop in the left groin the day before, following which the left leg became cyanotic and badly swollen.

In his case, examination of the left leg showed the same line of cyanotic demarcation at the groin as described in Case 1, but he also showed an extensive fungous or ringworm infection over the entire inner ankle and lower leg. There was also much inflammation in the tissues in this area. This case was thought to be a definite infectious thrombophlebitis and the patient was given four intravenous injections of gentian violet 0.5 per cent, six of Creohex and six doses of Edwenil subcutaneously.

In spite of all treatment and consultation the condition spread upward into the iliac veins, with an involvement of the right iliac and femoral veins and a septic lung embolus with later abscess formation. The patient finally died of a rupture of the lung abscess into the bronchus and an acute pneumothorax. At the autopsy a thrombus was found to be completely plugging the inferior vena cava, four inches above the bifurcation at the pelvic brim. This thrombus was firm and was of at least several days, duration.

The most important phase of the treatment of thrombophlebitis is its prophylaxis. This is accomplished by exercise and doing all those things in the individual case that will aid venous drainage. Tight abdominal postoperative binders should be avoided as much as possible. The patient should be urged to move the legs actively as early as possible and several times a day. Thyroid gland given before and after operation increases the circulatory rate. The patient should walk immediately after an injection treatment of varicose veins and be up and about the house every two hours after the preliminary ligation and injection of veins. This avoids the stasis in the deep veins of the calf which could be injured by the injected solution. In Sweden[9] a mortality rate of 0.33 per cent following the combined ligation and injection treatment has been reported. This is higher than for the former resection operation of years ago which was given as 0.26 per cent. This I am satisfied is due to the surgeon demanding bed rest for his ligation cases.

For the active treatment of the individual case, elevation of the extremity and hot packs from toes to abdomen with the electric light baker at hour intervals four times daily seem to give the best results. Medication has been of little help. Sulfanilamide should be tried and in some cases the intravenous use of 0.5 per cent aqueous solution of gentian violet does seem to help.[7] Murphy[4] claims excellent results with mecholyl iontophoresis in the treatment of the chronically indurated and inflamed lower leg so commonly seen after phlebitis.

Summary

Thrombophlebitis of this particular type is in my experience very rare. The three cases presented were, however, seen this past year. Though radical surgery has been advised in the way of ligation of the vein above the thrombus,[5,6,8] I believe that the above method of expectant treatment is to be recommended.

Discussion

Dr. Carl O. Rice: Dr. McPheeters has described three very interesting cases. In view of the fact that this condition is relatively so uncommon, it is difficult to say a great deal about it.

It appears that these cases are a bit different from the ordinary milk leg, or infectious thrombophlebitis, which is not infrequently observed postpartum. The report of these cases suggests that at least two of them were not initiated on an infectious basis.

The first case seems to suggest that the thrombophlebitis was the result of the chemical irritation from the injected sodum morrhuate. On the other hand, one is inclined to speculate as to why it should occur in this case and not in thousands of others similarly.

When we investigate the causes of venous thrombosis, we find that they may be classified into three different groups.

1. These may be disorders in the vein wall (injuries, inflammation, etc.). Homans states that in large veins the initial change in the intima of the vein may not necessarily be present. He has described exploratory operations in cases with iliofemoral thrombophlebitis in which he found a definite exudative reaction about the common and external iliac arteries. This, he believes, might be considered a deep perivascular lymphangitis—the etiology of which he has not determined.

2. Disorders of the blood, chiefly in the form of dehydration, have been described as another cause for thrombophlebitis. Dehydrated and debilitated individuals more frequently develop thrombophlebitis than comparatively healthy persons.

3. Disorders of the venous return may be due to general circulatory failure, or to factors which cause the blood flow to be slowed up. Among these are, postoperative inactivity, immobilization of extremities, pelvic masses, etc. The anatomical position of the external iliac and the common iliac veins in passing behind their corresponding arteries may also be a

factor, in the inactive bed patient, in causing the delay in the venous return.

Homans has described the following different varieties of thrombophlebitis:

1. Deep (femoroiliac) thrombophlebitis, sometimes described as phlegmasia abladolens. This is a not uncommon type of thrombophlebitis. If it produces a great deal of swelling it indicates greater extensiveness. There may be instances in which a thrombus may exist and may break off, causing a pulmonary embolus without having given any evidence of its previous existence.
2. Deep peripheral thrombophlebitis, which involves the veins in the muscles of the leg.
3. Traumatic and infectious thrombophlebitis, which does not have its origin in varicose veins.
4. Thrombophlebitis in varicose veins.
5. Migrating thrombophlebitis. This is a condition in which the thrombus extends toward the heart within the vein, and lies attached at only one point. In endeavoring to explain these three cases which Dr. McPheeters has reported, it seems possible that in the first case this may have been a factor, with the migrating thrombus having taken its origin from the chemical thrombus below.

In the other two cases, it is difficult to state what might have been the origin. The second case may have been similar to those which Homans has described as having a perivascular lymphangitis. The third case in which there had been a varicose ulcer and infection, may have been an infectious thrombophlebitis.

I agree that the best treatment for these cases is that which Dr. McPheeters has described: elevation, dry heat and early graduated exercises.

* * *

Dr. H. O. McPheeters: In conclusion I wish to emphasize one point. The relief from the peripheral neuralgic pain was so complete and so easily obtained that next time I will inject the painful areas first and the varicose veins later.

THE THERAPEUTIC EXPEDIENTS IN THE MANAGEMENT OF ACUTE INFECTIONS OF THE EXTREMITIES

Owen H. Wangensteen, M.D.

Abstract

Immobilization and elevation are of the greatest importance in the treatment of acute infections of the extremities. The most rigid immobliization is best achieved by placing the extremity concerned in a plaster of paris cast including the body trunk. Immobilization reduces muscle movement to a minimum. It also decreases the risk of dissemination of infection via the lymphatics; in addition it also reduces lymph production.

Accompanying all infections of the soft tissues swelling occurs, in consequence of the capillary injury. The extent of the swelling is limited by the occurrence of a high tissue pressure or tension which tends to delimit filtration from the capillary bed. Elevation of an infected extremity in a fixed position as high above the heart level as can conveniently be done with comfort to the patient, succeeds in early reduction of the swelling. Swollen tissues favor spread of the infection.

Bier's hyperemia in the treatment of acute infections of the extremities is physiologically unsound in that it increases venous pressure and consequently capillary pressure and augments filtration of fluid from the capillaries into the tissues. Heat also accentuates capillary permeability and is not to be used with an infected extremity in a dependent position.

The relief which has attended elevation of an inflamed member in an elevated position has been striking. The essayist has the impression that less extensive surgery need be done if immobilization and elevation are employed early in the treatment of infection. In acute osteomyelitis a body plaster is applied with a window over the tender area. When evidence of a subcutaneous abscess is present, an incision is made. Joints are similarly immobilized but incisions are made early and drainage secured by positioning. Fresh burns are treated in plaster with vaselinized shirting over the burned area.

Discussion

Dr. J. M. Hayes: As Dr. Wangensteen has said, one important factor in the treatment of all acute infections is immobilization. I am going to confine my discussion to these very acute infections, in which you have a severe lymphangitis and adenitis, from fifteen to twenty hours after a small wound on the extremities becomes infected.

Many years ago after spending a year in the University Hospital, I went out to practice in the country. In one particular area, not far from where I was located, it seemed that an epidemic of severe streptococcus infections developed. In a short period of time a large number of these cases came in with severe infections. It seemed that almost every one who got a slight pin prick got an infection.

This took place during harvesting and threshing. These patients were mostly farmers and you usually couldn't get one of them into the hospital, until he was ready to drop. We used all the hot applications we had ever heard of but our results were not good.

About this time I read a statement in Ochsner's textbook of surgery, stating that he never had a crippled or deformed hand or loss of life, not even had to amputate a finger, since he learned of this method of treating acute infections of the extremities. I went to Chicago and went out to the Augustana Hospital. Here the late Dr. A. J. Ochsner was just putting one of these dressings on a leg. He told us at that time that his brother, Dr. Ed. Ochsner, had many years ago before observed the application of this dressing in the out-patient department of Cook County Hospital. He didn't even mention the name of the man who applied it. This man only used a saturated solution of boric acid on the dressing but obtained results that attracted Dr. Ochsner. Together with Dr. Kahlenberg, more recently of the University of Wisconsin, he determined to find out more about the use of this dressing. They found with this dressing applied to the extremity, boric acid appeared in the urine in a very short time. Later A. J. Ochsner suggested

the addition of alcohol and phenol, much the same as the solution we use now.

Before application of this dressing with this latter solution they took material from the infected wound and injected it into the peritoneal cavity of a guinea pig and killed him in twenty-four hours. After the application of this dressing for forty-eight hours, they again took material from the wound and injected it into the peritoneal cavity of a guinea pig and it didn't even make him sick. We have verified these experiments to a small degree and have obtained the same results.

The solution we use now we call Modified Ochsner Solution. There is a formula for a solution dispensed by druggists called Ochsner Solution. This solution apparently was put in there by mistake. It is dangerous and should not be used. The Modified Ochsner Solution may be used on the skin of an infant for forty-eight hours with no bad results.

I have talked about this dressing for many years in the out-patient department of the University. Dr. Hirshfelder has repeatedly said this solution would not penetrate the tissues more than one-half a centimeter. He is right in the way he applied it but with this dressing the resistant part of the skin is soon mascerated to such a high degree that the solution readily penetrates the tissues. This has been definitely proven. I know this seems like an extravagant statement to some, but when we get one of these cases within the first forty-eight hours of the onset of infection, we promise the patient definitely that we can stop the spread of the infection by the application of this dressing for forty-eight hours.

For the details of the treatment I refer you to MINNESOTA MEDICINE, volume 16, page 255, (April) 1933.

CLASSIFIED ADVERTISING

CO-TENANT WANTED

To share with one other physician the space, equipment and technical service of his present completely furnished and equipped office in the Lowry Medical Arts Building, St. Paul.

A BARGAIN IN OFFICE SPACE, FACILITIES AND SERVICE
$100.00 per month includes:

1. Individual office and consultation room, reception room, laboratory and additional examining rooms.
2. Competent secretary and bookkeeper.
3. Experienced clinical laboratory technician.
4. X-ray equipment.
5. Telephone.
6. Electricity, gas and other Building Company services.

THE IMPORTANCE OF IMMOBILIZATION AND POSTURE IN THE TREATMENT OF ACUTE INFECTIONS OF THE EXTREMITIES*

OWEN H. WANGENSTEEN, M.D.

Minneapolis, Minnesota

IN THE management of acute pyogenic infections, the objective is plain, but by what ends that purpose is best served is not so obvious. Experience has suggested certain expedients which have become generally adopted in practice. It has been difficult to evaluate critically what the virtues of these tried remedial agents are. Surgeons individually have continued especially those therapeutic measures which have appeared to effect the end-result most favorably.

Rest, hot packs, incision and drainage have constituted the essentials of the usual surgical treatment of acute pyogenic infections of the extremities. Biers' hyperemia and roentgen treatment have their enthusiastic supporters. Surgeons generally have become considerably more withholding in the employment of incisions in the treatment of infections, limiting their use almost entirely to the evacuation of localized pus. Time was not so long ago when incisions were used freely in the treatment of cellulitis. Surgeons have learned from their own experience that these often did harm and rarely accomplished any good.

During the period of the World War, surgeons reverted again to the employment of antiseptics in wound management. Aseptic surgery, which followed so closely upon the Listerian scheme, displaced largely the use of antiseptic agents in the treatment of infected wounds. Like the use of ill-timed incisions, they often did more harm than good. With the development of Dakin's solution and the Carrel technic of its employment, it appeared that the chemical Messiah had been discovered. Surgeons in high places who spoke with authority acclaimed its accomplishments. Said the late W. W. Keen: "Lister taught us above all how to *prevent* infection; Dakin and Carrel, following Lister's principle, have taught us how to conquer even rampant infection. . . . Prevention and cure both are now ours." Such statements are now only of interest as a matter of record but serve to indicate how even the best oriented may be deceived by new things. Most surgeons have learned that Dakin's solution, like incisions, will not accomplish localization of infection; only the natural defense mechanism of the body can do that. To be certain, Dakin's solution has real value, but chiefly in accelerating clearing up of an infection which the tissues have conquered already.

Anyone who reads the literature of infection of the early decade of this century, cannot escape the impression that an immunologic specific would soon be available for every bacterial disease. This hope which seemed practically assured never materialized. After a few triumphant exploits, the new science of bacteriology, which in a relatively short period of time revolutionized the practice of medicine, seemed to have become therapeutically sterile and no further conquests were forthcoming. Yet to the development of specific immunologic or pharmacologic aids, surgeons, whose office it is to deal with acute pyogenic infections, look with anxiety and hope; for we know that our accomplishment in the management of spreading infections is not great. Our task is essentially to help the natural de-

fense mechanism of the body in its conflict with the infection and to evacuate pus when localized suppuration has occurred.

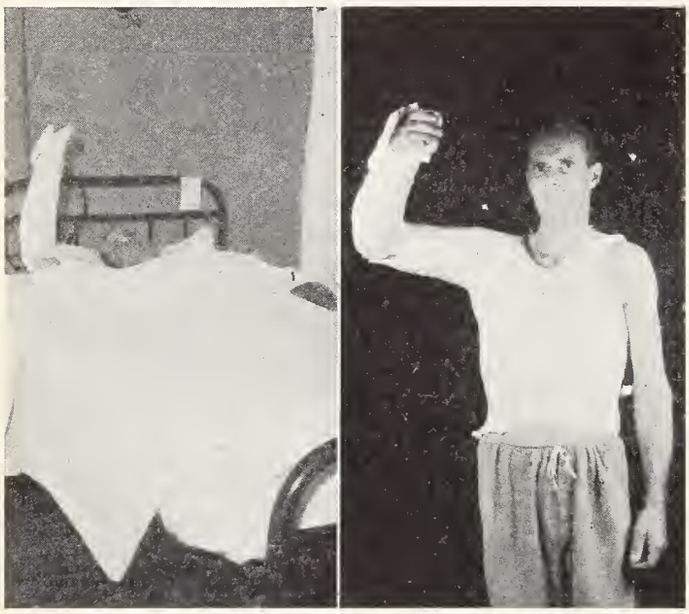

Fig. 1. (*left*) Immobilization of arm in a body plaster spica for phlegmonous inflammation of the hand. (*right*) Same patient ambulant. It is important that the extremity be placed in such a position that the hand will have maximum elevation in both recumbent and erect postures.

Immobilization

About four years ago, a young woman came under my observation who had sustained a compound fracture and a virulent phlegmon of the left thigh. After many consultations, short incisions for drainage were replaced by extensive incisions. These measures and employment of the Carrel-Dakin technic of wound irrigation all proved fruitless. Hectic fever continued and it appeared that we had lost our opportunity to save the woman's life by an earlier amputation. As a last gesture, a plaster spica cast, extending as high as the nipples and including both lower extremities, was applied—windows being left in for drainage. Despite adequate skeletal traction which had satisfactorily reduced the fracture, the relief from pain upon the application of the plaster was striking. In ten days the patient was afebrile and made a satisfactory recovery.

This experience was startling, and on occasion, when unsatisfactory results were had with orthodox methods of treating infections, as a matter of last resort, encasement in plaster was tried. The improvement attending its use suggested trial with the method as the initial mode of treatment. During the past two years, I have treated a large variety of acute infections in this manner, with windowed plaster casts. Among these are spreading infections of the soft tissues of the hands and feet including phlegmons, lymphangitis, phlebitis, acute osteomyelitis and suppurative arthritis. It has come in our clinic to be the standard method of treatment. In tenosynovitis, the necessity for early opening by incision of the tendon sheath still appears necessary. In established felons and paronychias, we have not employed immobilization in plaster. However, in all other varieties of hand infections immobilization of the hand and arm in a body plaster, in as great elevation as can be obtained conveniently, is regularly done. Latterly a severe burn of the trunk and lower limbs in a young child has been treated also in this manner. Vaselinized shirting was pulled over the burned lower extremities and trunk and a body plaster applied over all. The remarkable relief of pain was very pleasing to everyone. The child could be turned without discomfort and on the first change of plaster about three weeks later, the appearance of the burned area was very satisfactory—much of it had healed.

Immobilization in plaster, though it does not obliterate tonus or voluntary motion, does reduce movement to a minimum. The immobilization obtained by splints or traction does not begin to approximate the security and rigidity lent by adequate immobilization in plaster. The lymphatics, it is to be remembered, ramify in the fascias overlying the muscles. The importance of keeping muscles as quiet as is physically possible in phlegmonous inflammations is therefore understandable.

John Hilton, of Guy's Hospital in London, wrote a fascinating and informative treatise on Rest and Pain during the period of the Civil War in this country. Langenbeck suggested employment of windowed or bridged plaster casts in war wounds, and in the Franco-Prussian war, closed plaster casts were used by Ernst V. Bergmann in the treatment of gunshot wounds of joints, leaving the plasters on usually for about a period of a week. A short time later Dennis of New York (1884) pointed out the great value of immobilization in plaster in the treatment of compound fractures. With the advent of general acceptance of antiseptic and aseptic practices, this conservative plan fell largely into disuse, being replaced by more energetic technics (irrigations, et cetera), by the sur-

geon. Impressed with the futility of chemical wound management in localizing infection, Orr of Lincoln adopted rigid immobilization in plaster as a constant sequel to sequestrectomy for chronic osteomyelitis, shortly thereafter employing closed plaster casts and the massive vaseline pack together with extensive osteotomy as well, in the management of acute osteomyelitis.

Elevation

It soon became apparent that employment of elevation was a valuable addition to this mode of treatment of acute infections—particularly when the inflammation concerned the soft tissues. Increased relief of pain and quicker reduction of swelling were noted. Institution of rigid immobilization in a body cast with the extremity concerned in marked elevation occasionally made incision for the evacuation of exudate in soft tissues superfluous. Not uncommonly a single short incision sufficed in instances where one had anticipated doing considerably more. In paronychias where there is no hazard of dissemination of the infection, continuous steep elevation of the arm and hand on a suitable bed-side splint has been carried out with encouraging evidence of subsidence of the infection.

It is apparent that the patient must lie upon his back in order to secure the greatest elevation. If he sits up in bed, elevation of the lower extremity can not be obtained. (Incidentally, Fowler's position is much over-used by surgeons. I rarely employ it.) Raising the foot of the bed on a shock frame is a helpful means of obtaining elevation for the lower extremity when a body plaster is applied. For the thigh and leg the placement of staples in the cast permit it to be suspended at a steep angle by means of an overhead bed frame.* The upper extremity can be positioned easily in a condition favorable for lymph flow.

Hot Packs and Bier's Hyperemia

It is apparent that encasement of an extremity in plaster affords little opportunity for the application of heat. In consequence, I have come to neglect its use and can not feel that a worthwhile

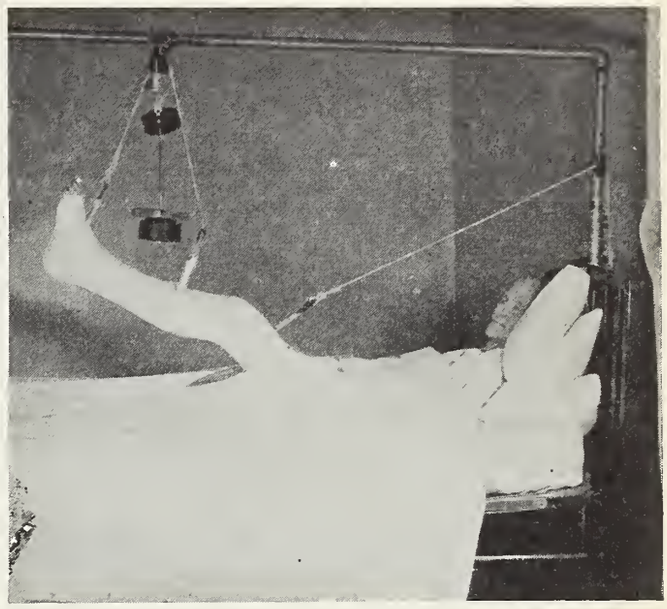

Fig. 2. A method for securing maximum elevation for an infection in the lower leg. When a body plaster cast is applied it is apparent that effectual elevation of the lower extremity can only be obtained by elevation of the foot of the bed.

therapeutic expedient has been lost thereby. The application of heat and employment of Bier's hyperemia are measures which increase swelling —objectives which, I have come to feel, are to be avoided in the treatment of acute pyogenic infections.

The experiments of Landis on capillary filtration throw considerable light on these matters. He has made direct measurements on capillary blood pressure and finds that a gradient in pressure obtains from the arterial to the venous end of the capillary. Mean capillary pressures at the base of the nail in man he found to be 45 cm. of water at the arterial end of the capillary loop and 22 cm. at the venous end. The ordinary colloid osmotic pressure of the blood in man is of the order of magnitude of 36 cms. of water. Measures which elevate capillary blood pressure therefore increase filtration into the tissues. Increases of venous pressure are directly reflected in the same degree in the capillary pressure. The swelling which occurs with dependency of an extremity or with the employment of heat or Bier's hyperemia is, therefore, readily understandable. The capillary injury which attends infection also results in increased permeability and augmented filtration of fluid. The only manner in which the tissues can limit filtration is through sufficient accumulation of

*I do not believe that maximum elevation of the lower extremity should be employed for long periods of time, particularly in older people. In the erect posture a patient with normal vessels has a blood pressure in his dorsalis pedis artery of 100 mm. Hg or more over that of the arm at heart level. The lower extremity therefore is not well accommodated to the lowering of systolic pressure which attends great elevation. However, fairly steep elevation is well tolerated and the warmth of the toes is a good indication of an adequate circulation. Elevation decreases venous pressure as well as systolic pressure—both of which in turn lower capillary pressure and decrease filtration. Parenthetically, I might add here, that it may prove that free use of the erect posture (which increases the hydrostatic force of systolic blood pressure) may be the best means of forcing blood through arteriosclerotic vessels before circulatory inadequacy sets in.

fluid to produce a high tissue tension which tends to keep the fluid in the vessels.

Agencies such as Bier's hyperemia, which

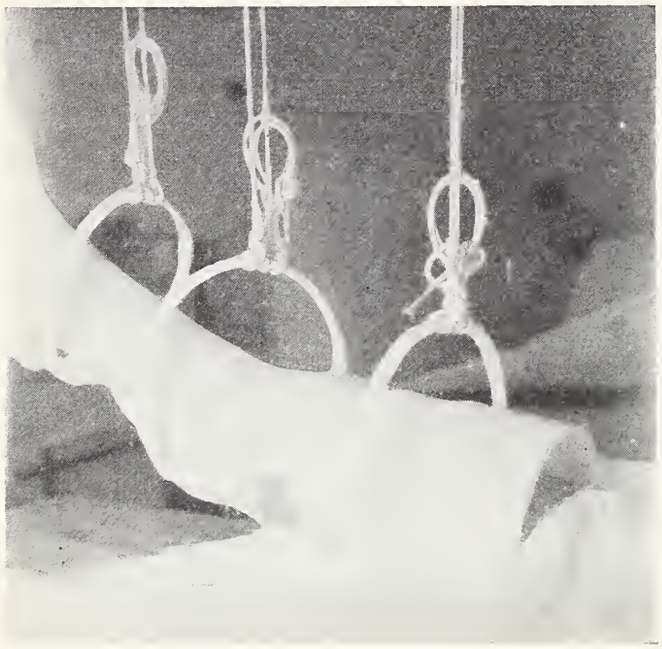

Fig. 3. This patient had a swelling of long standing attending a compound fracture. The reduction in swelling following elevation of the swollen member is evidenced in the separation evident between cast and upper surface of the thigh.

cause increases in venous pressure, probably abet the infectious process for it is well known that areas of swelling are predisposed to inflammation. Under increases of venous pressure lymph production is also increased. Great elevation of an injured or infected member above heart level will not suffice to prevent increased filtration in a damaged capillary bed. Yet with lymph outflow being favored by steep elevation it is apparent that swelling will be minimal unless the increased filtration is great. In the reduction of swellings of long standing in extremities as occur in malunited fracture and chronic inflammations of many varieties, I have come to feel that an inch of gravity operating for three days, will accomplish as much as three weeks of heat and massage.

Technic

I have elsewhere described in some detail[7] the mode of management. Here, for purposes of clarity, I only wish to mention briefly the manner in which instances of acute osteomyelitis and suppurative arthritis have been treated.

A patient with an acute osteomyelitis of the tibia is encased in a body plaster with a long leg cast on the side of the lesion. A short leg cast extends to the knee on the opposite leg. A window is cut in the plaster over the tender area. Only when there is evidence of a subcutaneous

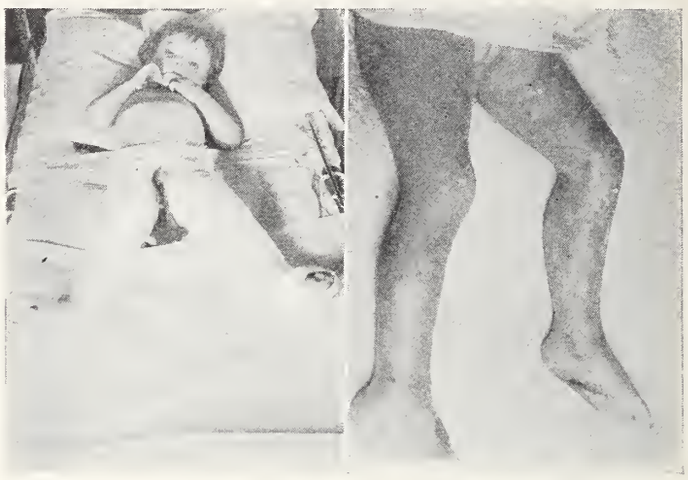

Fig. 4. (*left*) Second degree burn of the extremities encased in a plaster cast with sterile vaselinized shirting over the burned areas. (*right*) The situation one month later on removal of the cast; the burned area is nicely healed. Before the application of the cast the patient complained considerably of pain; following encasement in plaster the patient could be turned and managed without difficulty.

abscess is an incision made. In one instance (lower femur) because of persistence of severe pain despite immobilization and elevation, a single hole was made in the bone with a small gimlet before evidence of a subcutaneous abscess became apparent. Plasters are worn for a variable period, but usually until the skin is healed or drainage is minimal. As soon as the patient is afebrile, he is encouraged to move his extremity.

In suppurative arthritis, a body cast is applied similarly. A window of appropriate size is cut to permit aspiration of the joint (knee). If the temperature is not favorably influenced by daily aspiration of the exudate, short vertical incisions are made on either side of the patella after two or three days. A small rubber tube drain is placed down to the capsule. In order to secure the benefit of gravity drainage, the patient must lie on his face for several hours a day. Drainage is established for suppurative arthritis of the hip joint as soon as pus is obtained by aspiration. (Ober's posterior incision). Positioning in the cast to facilitate drainage is also important. Sulphanilamide may be given to advantage, for a large proportion of joint infections are streptococcal. The patient is encouraged to move his extremity as soon as he is afebrile. When movement in the plaster causes no pain and does not

produce fever, the cast should be removed and a wider range of motion encouraged.

Conclusions

The rôle of the surgeon in the management of acute infections of the extremities has been reviewed. It is pointed out that his chief objective should be to assist the natural defense mechanism of the body in overcoming or localizing the infection. Other than that his function is that of a pus evacuator—to incise an abscess when suppuration occurs.

The great virtue of rigid immobilization and elevation of the affected member in infection is described. It should be the aim of the surgeon to keep the infected extremity as quiet as physically possible; in addition he should, through employment of elevation, strive to keep swelling at a minimum. The attainment of these objectives serve the natural defense mechanism of the body in a most helpful manner.

THE IMMEDIATE AND SUBSEQUENT TREATMENT OF BURNS

RAYMOND F. HEDIN, M.D.†

Chicago, Illinois

IN THE past twelve years much progress has been made in the treatment of burns. Davidson's[12] discovery that tannic acid applied to burns formed a crust was outstanding in this field of surgery. Since then, the treatment of burns has been based on the surgical principle of making a "closed surface out of an open surface," without injury to tissue and consistent with early functional and cosmetic results.

In reviewing the literature on burns one finds the articles divided into two groups: those dealing with the factors involving the mortality and morbidity and those dealing with the treatment and care of burns. One is impressed with the controversy as to whether or not the morbidity and mortality in burns are due to toxic absorption or to the loss of vital body fluids. Robertson and Boyd[24] showed that toxic symptoms would be produced in eight hours if a normal animal were grafted with burned skin. Other investigators[20] have found that iodides are absorbed through burned surfaces. Rosenthal[25] reports that following burns there is a histamine-like substance in the blood stream capable of lowering blood pressure and causing a guinea pig's uterus to contract in Ringer's solution. Kapsinow[16] doubts that toxins can be absorbed through burned surfaces, as he was unable to find such evidence when phenolsulphonphthalein or strychnine was applied to the burned site. Blalock,[11] Underhill, Kapsinow, and Fiske[26] have shown that body fluids are lost through burned surfaces and that there is a concentration of fluids in the tissue surrounding burns. They point out that the so-called primary and secondary shocks following burns are due respectively to alteration in the relative and actual blood volume. The most convincing evidence seems to militate against the toxic absorption theory, although both factors may be involved.

In this paper an attempt will be made to outline the immediate and subsequent treatment of burns as practiced in the Children's Surgical Ward of the Cook County Hospital.

Tannic acid was used during the years 1934-1936 inclusive. During this period 395 patients were admitted for burns. Twelve of these died within twenty-four hours after the accident; eight died in the second twenty-four hour period and nineteen died after forty-eight hours, making a total of thirty-nine deaths or a mortality rate of approximately 10 per cent. It is obvious that statistics on burns are difficult to evaluate because of the many factors involved,

†Former Resident in Surgery, Cook County Hospital, and at present Resident in Surgery, Wesley Memorial Hospital, Chicago, Illinois.

namely: the cause, location, extent, degree, and the time the treatment is begun. The above figures are given to show the number of cases treated and the accompanying high mortality rate rather than to offer anything of statistical value.

Fig. 1. Method of debridement and careful, thorough cleansing prior to application of tannic acid-silver nitrate.

The deaths from burns as well as the cases requiring protracted hospitalization resulted chiefly from matches, coffee-pot and tea-kettle accidents. Many of these pitiful and tragic results, no doubt, could have been avoided if only a few precautions had been taken and if there had been a greater realization of the consequences of burns. From an economic standpoint it is easy to conceive how the financial status of a family with a moderate income could be completely shattered by such an accident requiring sometimes months of hospitalization.

Gentian violet has not been used because it has the disadvantage of staining everything with which it comes in contact and so adds to the nursing problem. Furthermore, the coagulum often cracks, thus allowing organisms to enter the burned area.

Picric acid preparations produce toxic symptoms when absorbed from extensive burned surfaces. Like gentian violet, it fails to form a firm, adherent crust. These objections prompted our use of tannic acid for the treatment of burns on our service.

From January, 1937, until October, 1937, the tannic acid-silver nitrate treatment of Bettman[2] was used in eighty-two consecutive cases. Two patients died during the first twenty-four period; one died in the second twenty-four hours and three died after forty-eight hours, making a total of six deaths in eighty-two cases, or a mortality rate of 7.3 per cent.

Fig. 2. (*Above*) Extensive burn showing the coagulum produced by the application of tannic acid-silver nitrate. Photograph taken two hours after accident. Note the apparent comfort of the patient. (*Below*) Posterior view of the patient.

It is the writer's opinion that the claims made by Bettman[2,3,4,5] are correct and the treatment should enjoy more widespread use. The important claims which have been substantiated by our own observations are:

1. The patient is safely carried over the critical first twenty-four hour period by the rapid tanning of the burned area which prevents the loss of body fluids.
2. Infection is prevented by the rapid drying of the tanned tissues.
3. The patient is made more comfortable.
4. The nursing problem is simplified, especially in the first twenty-four hours.
5. A thin, flexible coagulum is formed (Fig. 2a, 2b).
6. The kidneys and other organs are saved from the effects of fluid concentration and the absorption of toxins and infection.
7. The burned areas heal quickly, thereby shortening the period of hospitalization.

Immediate Treatment

Whether or not the patient is in a state of shock is of primary concern. The treatment of shock supersedes the treatment of the burns. Shock following burns is best treated by the judicious use of morphine, maintenance of body temperature, the administration of oral and parenteral fluids, and blood transfusion. Following

the improvement in the patient's general condition, the treatment to be used on the burned areas depends chiefly on the time that has elapsed since the accident and the gross contamination of the burned surface. If eight or ten hours have elapsed and the surface is so contaminated with grease, dirt, and clothing that it is likely that infection will result, then the burned areas had best be treated with moist saline dressings in an endeavor to promote drainage and sterilize the surface so that an early skin graft may be instituted. If the patient responds quickly to shock therapy and it is felt that the burned surface can be rendered clean, the treatment then is the same as if the patient had been seen immediately following the accident.

If the patient does not have symptoms or findings of shock, morphine is given in sufficient quantity to control pain and restlessness. In this regard, the respiratory rate serves as a reliable guide as to the dosage. The thorough cleansing of the patient at this time is of vital concern and negligence in this important step of the care predisposes to failure. To best attain this end, the disrobed patient is placed in a bath-tub which has a suspended false bottom (Fig. 1), which allows the escape of contaminated water into the tub drain. With this arrangement sterile sheets are placed under the patient, replacing soiled ones when necessary. In carrying out this cleansing bath, the surgeon and assistants wear caps, masks, gowns and gloves. Every effort is made to prevent the further contamination of an already contaminated field.

Benzine or other fat solvents are used to remove grease that usually has been applied to the burns before the patient enters the hospital. The patient is then given a thorough cleansing with white soap and sterile water. White soap has the advantage over green soap in being less irritating to the tissues (Koch).[18] The loose burned tissue is carefully removed and blebs are opened. The controversy[27] on the rationale of opening blebs is of long standing. We believe that to open the blebs and tan the underlying surface precludes the danger of future rupture and infection of blebs incident to nursing care. This cleansing process often requires an hour of meticulous care and patience to render the unfortunate victim grossly clean. Much depends upon this detail in the successful treatment of burns.

Following the thorough cleansing, the patient is placed in bed on a sterile sheet. The burned areas are then dried with an ordinary electric hair dryer in preparation for the tanning. At this time it is well to inspect carefully the surfaces because a definite idea may be gained as to the depths of the burns. A dull, grayish surface usually means destruction below the dermal layer which foretells a long hospitalization. However, as Davidson[12] pointed out, because of the loss of fluids the surface area involved is of more importance than the depth in the immediate treatment of burns. Berkow[1] has computed the surface area of the body as follows:

Fig. 3. Coagulum is allowed to dry under heat cradle covered by sterile sheet.

a. Trunk 40%
b. Lower extremities 38%
c. Upper extremities 16%
d. Head 6%

Underhill and his co-workers have shown that a patient weighing 150 pounds with one-sixth of the surface burned, may lose 3500 c.c. of blood serum in the first twenty-four hours. For this reason the quicker the "open surface can be made into a closed surface" the better for the patient. With the use of tannic acid followed by silver nitrate, as described by Bettman, this end may be accomplished in a few minutes.

When the surface is dried, a freshly made aqueous solution of 5 per cent tannic acid is sprayed on the surface by means of an atomizer. Immediately after the single spray, silver nitrate in 10 per cent solution is applied to the surface by means of cotton pledgets. There is very little

pain during this procedure. A firm, adherent, flexible crust results almost immediately. The patient is then placed under a heat cradle (Fig. 3), covered by a sterile sheet and taken to his room. Light bulbs may be added to the heat

Fig. 4. Daily tub baths are given to cleanse granulating surfaces of pus and débris in preparing them for skin grafts.

cradle to maintain the temperature at a constant level. Occasionally the patient is placed on a Bradford frame to facilitate subsequent nursing. In this event the frame is covered with sterile sheets.

If there is a widespread surface area burned, a substantial blood transfusion is given routinely. Like Gunn and Hillsman,[15] we believe that when there has been any oozing prior to the tanning, whole blood offers the patient the greatest benefit. The taking of oral fluids is encouraged and parenteral fluids are given as indicated. The most reliable criterion as to the adequate fluid intake is the urinary output. In a child if the output is 500 c.c. to 750 c.c. daily, the intake is adequate. In an adult 750 c.c. to 1000 c.c. usually indicates sufficient fluid intake. Of value in this regard is the erythrocyte count and hemoglobin reading, which may be elevated due to the relative or actual blood concentration.

Shortly after the crust is formed, the patient is comfortable (Fig. 2a, 2b) and will need no further medication to control pain and restlessness. It is indeed a pleasure to see patients in such comfort and tranquillity of mind in contrast to the agonies shown prior to being treated. The most amazing thing is that the transition has taken place in such a short space of time. The necessary nursing care is reduced to a minimum and is in direct contrast with the treatment required when tannic acid is used alone and when spraying is needed every fifteen minutes for twelve hours.

It has been suggested that argyria may result from absorption but it has not been observed in our series of cases.

The eyelids are the only region not treated with tannic acid and silver nitrate. It would be impractical to splint the eyelids with the coagulum and in these regions bland ointments are best.

Minor burns lend themselves well to the tannic acid-silver nitrate treatment and can effectively be treated in the home or office.

Subsequent Treatment

Daily urine examinations are made in all burn cases. Albuminuria is rarely found even in the most extensive burns. A careful examination of the crust is made daily to ascertain any retention of pus. The temperature chart and leukocyte count forewarn of infection. If no infection develops, the crusts loosen and may be removed in two or three weeks, leaving behind a completely healed surface. If pus is found along the edges or anywhere under the crust, the overlying covering is immediately cut away in order to prevent the undermining of the entire coagulum. Moist saline dressings are applied to these areas to promote adequate drainage. These dressings are moistened and changed as often as necessary. Care at this stage may save the remainder of the covered areas from becoming infected.

Should the entire surface become infected, in spite of all the previously mentioned precautions, the patient (Fig. 4) is placed in a clean bath-tub and the crusts are gently removed by soaking in warm water to which soda has been added. When this unfortunate and not infrequent complication occurs, an attempt is made to get the surface in a suitable condition for an early skin graft. This objective is gained by giving the patient daily soaks in a bath-tub, at which time the dressings are soaked off less painfully, and the infected areas are carefully cleansed of pus

and debris. Moist saline dressings are then applied. Blair and Brown[8] have stated that they arouse the fighting forces of the surrounding tissue, provide adequate drainage and allay pain. Great care is taken in applying these dressings. Moistened strips of fine meshed gauze are placed next to the infected surface. The fine pattern of this gauze prevents granulations from growing up through the mesh.[17] In this way the granulations are preserved rather than traumatized and there is no bleeding encountered when the dressings are changed. This smooth covering of fine meshed gauze is then covered by dressings moistened with saline. They are evenly applied and are thick enough to prevent soiling. Rubber tubing in which holes have been cut may be incorporated in the dressing and sterile saline may be instilled. Care is taken to see that the dressings do not dry in place. They should be moistened sufficiently to be absorbent. Excessively wet dressings cause the surrounding tissues to become macerated. Firm, even pressure is maintained by moistened, soft, sea sponges which are held in place by wide bandages. Adhesive tape and safety pins are so placed that the dressings are comfortable and will remain firm and stationary. Where a moving part is involved, such as the back, chest and abdomen, a wide elastic bandage tends to hold the dressing well in place.

Antiseptics are not used on granulating surfaces because they are irritating and tend to destroy the tissue. However, when necrotic tissue covers the infected area, freshly made Dakin's solution is used in place of saline for a few days. This results in a rapid separation of the necrotic tissues.[19] Vaseline and other ointments are not used on granulating surfaces because they do not give the stimulation afforded by a moist saline dressing. Vaseline dressings prevent adequate drainage by allowing pus to accumulate on the infected surface.

Whenever dressings are changed great care is exercised in not introducing new organisms on the surface. It was our experience during March, 1937, that five out of seven burn cases developed fever and pus on relatively clean surfaces. All of these cases had been cared for by an attendant who was suffering from a pharyngitis. The importance of adequate masking has been properly stressed by Meleney,[21] Davis,[14] and others.

Throughout the period that the granulation tissues are being prepared for a skin graft, every effort is made to build up the patient's general physical condition. Precautions should be taken against exposure to upper respiratory infections which are so prevalent during winter and spring months.[21] A palatable, nourishing diet is beneficial. When the healing powers of the patient seem to be at a stand-still, blood transfusions[23] often provide the necessary impetus to hasten recovery.

As Blair and Brown[7] have so excellently stated, "skin grafting must be early, quick, permanent and conserve health, comfort, function, time and money." The proper time to cover the granulation surfaces with a skin graft is based on the patient's general physical condition and the condition of the site to be grafted. The patient must be able to withstand a short, general anesthetic. It should be felt that the healing potentialities will, with a degree of certainty, assure a "take" of the graft. The granulation surfaces should appear bright red, indicating their splendid vascularity. They should be flat and firm.[22] Bacterial counts are not made because such procedures are indefinite and offer little clinical information. The surrounding tissue should not be red and indurated. When granulations are dull, grayish red in color and appear to be exuberant, jelly-like, with a large amount of drainage, they do not lend themselves to successful skin grafting and had best be further prepared.

Type of Graft

The best type of graft to employ should be one that will most quickly convert the open granulating surface into a closed surface with the best functional and cosmetic results. The graft that best fulfills these requirements, in the majority of cases, is the Blair split-graft of intermediate thickness. This type of graft is easily and quickly obtained in sizes large enough to cover completely the granulating surfaces. It is of uniform thickness, which adds to the cosmetic results. The fact that this type of graft includes a substantial portion of the corium prevents it from contracting, thereby giving a good functional result. The donor site heals readily without scarring. With this graft the "take" is remarkably good on surfaces that are only relatively clean.

Ollier-Thiersch grafts include a very small portion of the corium and although the "take" is usually excellent, because of their thinness, they offer little protection. Also, on a movable surface they may contract up to as much as 60 per cent of their original size. Then too, they are not any easier nor any quicker to obtain than the split-graft of intermediate thickness.

Reverdin grafts include the epidermis with a very small portion of the corium. They are placed on the granulating surface as islands with the hope that epithelization will take place and connect them. They fail to close the surface completely.

Davis'[13] small, thick grafts include varying thicknesses in each graft. Because of the technic by which they are obtained (cutting the base of a piece of skin that has been elevated by a needle) they are of full thickness in the center and thin at the periphery. Like the Reverdin graft, they are but islands on the site to be grafted and fail to make a complete covering. To place the islands on a large, granulating surface by this type of graft is time-consuming. This type of graft, when healed, gives a spotty appearance because of the uneven thickness. The donor site, from which these grafts are taken, is left with punched-out scars which also give an unsightly appearance.

"Seed" grafts almost invariably become smothered by exuberant granulation tissue.

Full thickness grafts and pedunculated flaps[10] are not suitable for granulating surfaces. They are best utilized in reconstructive surgery, as in freeing contractions, where fresh, raw surfaces are made.

The split graft of intermediate thickness with its advantages, as stated above, has, in our hands, been the most effective in covering defects resulting from burns. The technic of the use of this type of graft on our service at Cook County Hospital is outlined as follows:

A general anesthetic is given.

Selection of Donor Site

A site is chosen that will provide the adequate amount of skin to cover the defect. The skin is usually taken from the outer or inner surfaces of the thighs. When these surfaces are unavailable the buttocks or abdomen are used. The skin on the back does not lend itself well for grafting. It should be borne in mind that hair may continue to grow if the grafts are taken from a region containing hair. The donor site must be free of any infection. Furuncles, paronychia and other infections, even some distance removed from the field of surgery, may cause infection and destroy the hope for a successful graft.

Preparation of Donor Site

The surface is gently washed with white soap and water, using coarse cotton to cleanse mechanically the site. This preparation requires ten minutes or longer and care is taken not to traumatize the skin by too vigorous rubbing. Antiseptics are not used in this preparation as they destroy tissue.

Preparation of Receptor Site

The receptor site is also prepared with white soap and sterile water. When the surrounding tissues are washed, the granulations are covered so as not to submit them to undue contamination. The granulations are gently washed, care being taken not to cause trauma. The granulations down to the capillary layer, as well as indurated edges immediately around the site, are removed by means of a razor. In this way the granulations are made flat and even. Firm pressure applied to a saline dressing controls hemostasis until the graft is applied. When persistent bleeders are encountered, they are ligated with fine silk. Curretting[9] of granulations to freshen the surface should not be done as the resulting surface is left ragged and uneven.

Skin Grafting

A thin film of xeroform ointment is spread over the donor site. A Blair knife and suction traction are used to remove the skin. Firm tension on both sides facilitates the cutting of the grafts (Fig. 5). An endeavor is made to cut grafts which will completely cover the defect and slightly overlap its borders. When the site to be covered is of such magnitude that many grafts are required, they are placed so that each graft is overlapped by its neighbor, making a complete covering. A continuous horsehair suture is used to baste the graft down and hold it in place. When the surface is completely covered, several small holes are made in the graft by means of a sharp, pointed knife. This allows blood and serum to escape which might otherwise undermine the grafts. The entire grafted

surface is then covered with a smooth, single layer of xeroform fine meshed gauze. The preparation used to impregnate this gauze is composed of 3 per cent xeroform in a vaseline base and is thought by some to limit the growth of staphylococci. Over this smooth covering is applied a large gauze dressing which is bandaged under moderate pressure. Soft, moist, sea sponges[6] form the best means of applying pressure over an irregular surface. They are occasionally split so as to fit the surface and are so placed that firm pressure is exerted over the entire graft. It is of paramount importance that the entire pressure dressing is securely placed to prevent the graft from moving. This is accomplished by the use of wide bandage which is anchored by adhesive tape and numerous safety pins. Rubber tubes are incorporated in the dressing through which saline is instilled in an endeavor to keep the dressing from drying out. Meticulous care is taken in the application of the sea sponges. As Blair[6] has emphasized, properly applied mechanical pressure controls oozing, eliminates dead spaces, limits venous and lymph stasis and prevents plastic material from pouring into the area.

The donor site is also covered with a layer of xeroform fine meshed gauze and a firm gauze dressing which is securely wrapped with bandage. It is best not to disturb the dressing on the donor site for ten days, at which time it is usually completely healed.

The dressings on the grafted site are removed on the sixth day. At this time great patience is needed in slowly removing the dressing so that the grafts will not be torn from their beds. The use of sterile cotton applicators facilitates the separation of the xeroform gauze from the graft and the wiping off of any pus found on the surface.

Sea sponge pressure is used in the daily change of dressings for the next few days to prevent bleb formation. Following the successful grafting of skin, gentle massage is encouraged.

Summary and Conclusions

1. The morbidity and mortality resulting from burns are probably caused by both absorption of toxic material and the loss of vital body fluids. There is convincing evidence to show that, perhaps, the latter cause is the greater factor.

2. The tannic acid treatment of burns was used in 395 cases admitted to the Children's Surgical Ward at Cook County Hospital during the period 1934-1936 inclusive. There were thirty-nine deaths or a mortality rate of 10 per cent, showing the disastrous consequences of burns.

Fig. 5. Method of removing skin by means of Blair knife and suction traction.

3. In the nine month period beginning January 1, 1937, eighty-two consecutive cases of burns were treated by the tannic acid-silver nitrate method of Bettman. Our clinical observations confirm the claims made by Bettman for this therapy.

4. The importance of the initial cleansing with white soap and sterile water is stressed. When properly done this lessens the chances of subsequent infection.

5. Infection frequently complicates the treatment of burns. This is best dealt with by daily cleansing baths and moist dressings. The point is made that granulations are not traumatized when covered by a layer of fine meshed gauze. Sea sponges serve as the best means of applying mechanical pressure. With the intelligent use of these agents, infected granulations are quickly and effectively prepared for skin grafting.

6. The various types of skin grafts are briefly outlined. On our service the use of the split-graft of intermediate thickness, described by Blair and Brown, has proven to be the quickest and most effective method of providing a permanent and complete covering to a granulating surface.

7. The technic for using this type of graft is given. The importance of a firm pressure dressing over the area grafted is discussed.

I wish to thank Dr. Sumner L. Koch, Dr. Gatewood, and Dr. E. M. Miller for their co-operation and instruction given me regarding the treatment of burns.

ERRORS IN THE DIAGNOSIS AND TREATMENT OF HYPERTHYROIDISM

ARNOLD S. JACKSON, M.D.

Madison, Wisconsin

THE basis of this paper is a study of one hundred cases incorrectly diagnosed as hyperthyroidism previous to our examination. In every instance, thyroidectomy had been advised for relief of symptoms, but in no case was it possible for us to corroborate the diagnosis of toxic goiter. In none of the one hundred patients was surgery performed nor has the need for such ever been established. This study was begun in 1929 so that in many cases at least five years have elapsed since the error in diagnosis was determined. Recently a follow-up letter showed that many had completely recovered and that none was suffering from hyperthyroidism. Most of the patients were cases of nervous and physical exhaustion.

Not long ago the reverse of this error in diagnosis was true. Advanced cases of hyperthyroidism long overlooked and long treated as cardiac, gastro-intestinal disorders and other conditions were brought to the surgeon for cure. Within two decades a goiter-ignorant profession has become very goiter-conscious in contrast to the situation a few years ago when the textbooks and medical schools were vaguely informative on this subject. They variously classified goiter as outward, inward, cystic, calcareous, nodular, irregular, physiological, et cetera. It was generally believed and taught that iodine was contraindicated in exophthalmic goiter. This notion had become popular because Kocher reported ill effects from the widespread use of iodine in the treatment of goiter in Switzerland. The resulting condition was termed Iodine Basedow and since the latter's name and exophthalmic goiter were synonymous, it was felt that iodine might initiate or aggravate the disease.

Today we know that this is not the case and that iodine in the presence of adenomatous goiter may precipitate hyperthyroidism but not exophthalmic goiter, although some still refuse to admit it. When I presented this idea before the American Association for the Study of Goiter in 1924,[3,4] the subject was debated and the term "iodine hyperthyroidism" was criticized. Now, however, the literature generally supports this contention. In a recent study,[2] it was shown by Freeman and the writer that in

*From the Jackson Clinic, Madison, Wisconsin. Presented before the Hennepin County Medical Society, Minneapolis, Minnesota, November 1, 1937.

a series of 279 cases of toxic adenoma, the disease was aggravated in 38 per cent by the use of iodine.

Much of this early confusion regarding the diagnosis and treatment of goiter has been clarified by the work of the American Association for the Study of Goiter, by Henry Plummer and others. Whereas twenty years ago there was not a satisfactory text on goiter, today there are several. Metabolism machines were unknown before the World War except in the scientific laboratory; today their use is widespread throughout the profession.

As a result of this great increase in knowledge of thyroid disease, our diagnostic sense has become attuned to the point that long standing hyperthyroidism is becoming a rarity. The same is true of pronounced exophthalmos, thyroid crises, huge goiters, and other manifestations of neglect. Unfortunately, the pendulum is swinging too far and patients with possible incipient hyperthyroidism, nervous and physical exhaustion, and the menopause, are advised to have a thyroidectomy. Has not the time arrived to stop this? If one department of an institution can report one hundred such cases observed over a short period of time, the number subjected to needless thyroid surgery throughout the country each year must be considerable.

From a study of these one hundred cases, I would place the source of error in diagnosis on the following factors: inadequate knowledge of the differential diagnosis of true and pseudo-hyperthyroidism; failure to elicit essential facts in the history; inaccuracy of the metabolism test or its interpretation; neglect in observing important physical findings; failure to try the iodine test; and the mistake of considering thyroidectomy an emergency operation.

If the important facts in the history such as weight loss together with an increased appetite, weakness in the knees on climbing stairs, pounding of the heart even at rest, heat intolerance, and emotionalism are not obtained, one should hesitate to make a diagnosis of hyperthyroidism. If physical examination reveals a normal appearing thyroid gland, and the absence of a thrill or bruit, together with a normal pulse pressure, hyperthyroidism should be excluded. Yet the mere complaint of tightness in the neck, so typical of nervous and physical exhaustion, large eyes, a full neck, a coffee or nicotine tremor of the hands, and a history of palpitation and insomnia, often seem to be sufficient to warrant

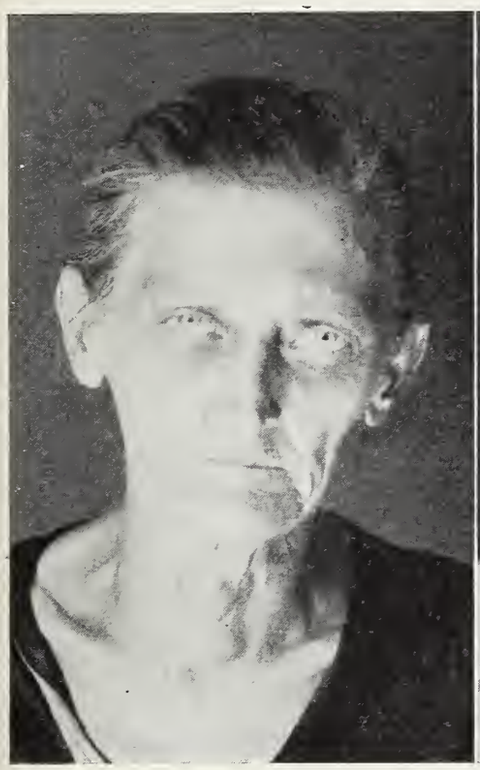

Fig. 1. Iodine-fast exophthalmic goiter. Patient had been taking Lugol's solution for six months.

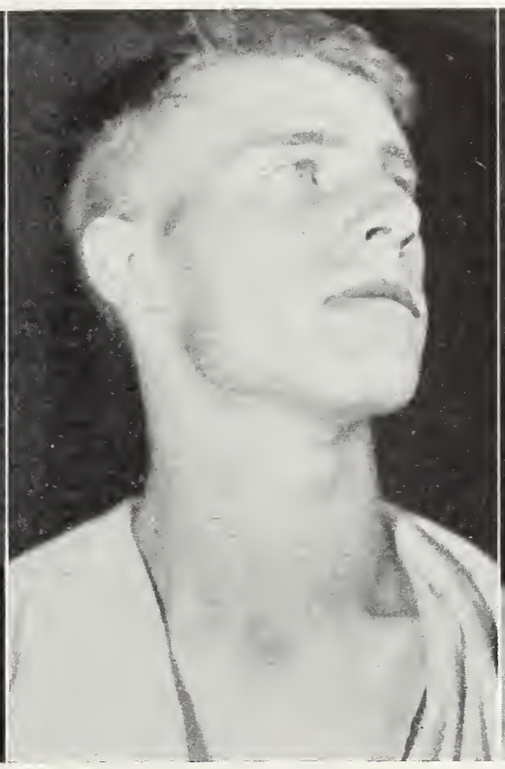

Fig. 2. Colloid goiter diagnosed as hyperthyroidism elsewhere and thyroidectomy advised.

Fig. 3. Colloid goiter shows symmetrical enlargement of the thyroid gland. Thyroidectomy had been advised because of elevation of basal metabolic rate, nervousness and tremor.

a diagnosis of hyperthyroidism. Various remedies such as thyroid therapy, iodine, salves, x-ray, radium, beads, injections, massage, and thyroidectomy are advised.

If doubt exists as to diagnosis final judgment is often reserved pending the outcome of the metabolism test. Such evidently was the case in fifty-seven of one hundred patients in this study since the rate had been reported above normal. In one instance, the rate was said to have been plus 94 per cent. In another it was reported to have been plus 55 per cent, yet our metabolism studies in all these cases indicated a normal condition of the thyroid gland.

The metabolism test is responsible for many errors in diagnosis. The test may be inaccurate because the machine is obsolete or has leaks, or because the technician errs, or, most important, its interpretation may be incorrect. Food, rapid breathing, fever, and nervousness are other factors which lead to error. If the patient's nose is tightly pinched with a clip, he will breathe too rapidly and the test will register higher than it would under normal conditions. This frequent source of error is generally overlooked.

One should not allow his judgment to be misled by any metabolic report. Last week I saw a middle aged woman who had recorded a test of over plus 25 per cent on three occasions. This was similar to her record at another laboratory, yet I feel certain that the patient is not hyperthyroid. Certainly surgery is not indicated on the mere basis of these reports. This patient was sent home for a month's rest. If she is hyperthyroid, it will soon become evidenced by a loss of weight, increase in the pulse pressure and elevation of the metabolic rate. That will be sufficient time to think of surgery.

Two years ago a patient came from New York City to consult about a goiter operation which he had been advised to have. Much to his surprise and apparent disappointment, his thyroid gland was found to be normal and he was told that he did not need an operation, but was advised to have more recreation such as golf. Recently he wrote, "Following your advice, I have taken up golf, feeling at the time that I was more or less swapping goiter for golf. After the game I played today, I am not so sure I wouldn't just as soon have the goiter."

Before seeing a patient, certain points in the history are helpful in determining a diagnosis. If he is under thirty years of age, the possibility of toxic adenoma can be eliminated because adenomas rarely become toxic in early life. A normal or only slightly elevated systolic pressure corroborates this tentative opinion. One must then determine whether or not he is dealing with a case of exophthalmic goiter. Probably 60 per cent of the patients whom I see in consultation have functional nervous complaints so that they already have two strikes called before I see them. Many complain of tightness in the neck and choking sensations which they believe are due to goiter. These are not typical symptoms of the disease, but those associated with a tense nervous system. This tenseness is often found in school teachers, stenographers, women at the menopause, and occasionally in business executives. It is intensified by repetition of tasks, by long hours of duty, by stimulants (particularly coffee), excessive use of nicotine, and by lack of rest, relaxation, and vacations. The tenseness of the nerves of these people may be likened to the sensation they receive when a rubber band is stretched tightly across their thyroid glands. What so many of them need is not the removal of part of their thyroid gland, but a change in environment.

It is exceptional if the history does not show that a loss of weight has been accompanied by a good or even ravenous appetite in exophthalmic goiter; whereas in patients with nervous or physical exhaustion, anorexia is the rule. The latter also are usually tired and pepless, while in the early stage of the former the reverse is true. When the patient walks into my office, I am interested in his actions. If he is restless, if he continually shifts his hands and feet about, and if he seems to forget things as soon as I say them, I suspect exophthalmic goiter.

Finally, when we come to the physical examination, the blood pressure findings are important. The presence of a low diastolic pressure is very suggestive of exophthalmic goiter, provided aortic insufficiency can be ruled out. Thrills and bruits are present in two out of three cases of Graves' disease after three months. They are not found in neurasthenia, physical exhaustion or even in toxic adenoma. The quadriceps test is of value in eliminating sources of error in diagnosing hyperthyroidism.

If the history and physical examinations still leave the diagnosis in doubt, if the metabolism

test is plus 30 per cent or more, what should be done? The patient may be given an iodine test for ten days and if exophthalmic goiter is present, there should be a gain in weight and a lowering of the rate. As a further check, the iodine may be stopped, thereby aggravating the symptoms. That should be sufficient evidence to warrant a diagnosis of hyperthyroidism and surgical treatment.

Unfortunately our errors in the diagnosis of hyperthroidism are not easily detected by the pathologist. In looking through his microscope, he is unable to tell us whether or not an adenomatous goiter is toxic or non-toxic. Moreover since the advent of Lugol's solution, an exophthalmic goiter which has been saturated with iodine may have all the gross and microscopic appearances of a colloid goiter. Careful search will usually reveal small areas of hyperplasia and infolding of the epithelium.

Errors in the treatment of hyperthyroidism are frequently attended with diastrous consequences. In spite of everything that has been said and written about the danger of the prolonged use of iodine in exophthalmic goiter, iodine-fast cases are still coming to surgery. The risk of operation is such that I seldom attempt anything but a two-stage thyroidectomy on these patients. Recently I had occasion to regret attempting even this much and, if given a second choice, would resort to a ligation, a procedure which I abandoned in 1925.

Since two out of three cases of toxic adenoma will improve on iodine, it should be given preoperatively as a routine. The cases not benefited will be only slightly affected in the short period of preparation.

Operative and postoperative complications such as laryngeal nerve paralysis, tetany, hemorrhage, pneumonia, and tracheitis will be lessened by the use of superficial cervical nerve block anesthesia. I have seen several fatalities which occurred following thyroidectomy for exophthalmic goiter where either through ignorance or mistake the patient was given insufficient amounts of iodine or none at all. This statement is made despite a recent article to the contrary by Davison and Aries.[1] A study of this treatise will show that they were apparently dealing in several instances with cases of toxic adenoma rather than exophthalmic goiter. The postoperative use of iodine is of but small consequence in toxic adenomas. In 1923 I showed that iodine in considerable amounts was important in the immediate postoperative treatment of exophthalmic goiter in order to combat hyperthyroidism. In the treatment of a considerable group of cases since that time I have seen nothing to alter this opinion.

Toxic adenomas rarely recur following subtotal thyroidectomy, but the average rate of recurrence for exophthalmic goiter throughout the country is probably about 10 per cent. This is largely due to failure to remove sufficient hyperplastic tissue at the time of operation and lack of proper postoperative care. Iodine should be continued in small amounts for three months; coffee and other stimulants should be prohibited; there should be a return to normal weight within three months after thyroidectomy; activity should be somewhat restricted, and relaxation should be stressed. The progress of recovery should be gauged by metabolic tests. Observance of these factors will tend to curtail the number of disappointing end-results of surgery.

In conclusion, I believe that this report of one hundred cases of error in diagnosis emphasizes the importance of a careful study of patients suspected of having hyperthyroidism. Thyroidectomy should not be considered until such conditions as nervous and physical exhaustion have been eliminated, and hyperthyroidism has been proved to exist. Possible errors in metabolism studies must not be overlooked, and the iodine test should be tried in doubtful cases. Finally, I believe that the diagnosis of hyperthyroidism is a continual challenge to us as physicians and surgeons, and, in order to maintain our highest ideals, thyroid surgery should be performed only when it is truly indicated.

SOME ATTEMPTED LEGISLATIVE SOLUTIONS TO THE PROBLEMS OF MEDICAL CARE*

THOMAS V. McDAVITT

Bureau of Legal Medicine and Legislation, American Medical Association

Chicago, Illinois

IT IS apparent that concerted efforts are being made in the United States to establish forms of medical practice totally at variance with the individualized practice of medicine, which has produced in this country a system of medical care unmatched elsewhere—unmatched not only in its scientific excellence but also in the universality of its distribution.

Some of the particular factors to which American medicine owes its eminence are obvious. We know, for instance, that individual initiative, unhampered by bureaucratic or political control, together with a reasonable prospect for making a decent livelihood for self and dependents, is an essential of scientific achievement in medicine as in all other fields of service. We know, also, that the relation of physician and patient has played a part of incalculable value because the practice of medicine is, and probably always will be, an art as well as a science. It will not, it can not, render its greatest benefit if it becomes merely a cold, calculating, impersonal application of scientific truths or half truths. Yet the legislative proposals made to change the form of medical practice would do away with these very essentials.

Let no one assume, because of the variety of proposals advanced, that American medicine has failed, that a vast proportion of our people are without adequate care, and that even an appreciable portion of the people are dissatisfied with the job American medicine has done and is doing. The fact, however, that there is really no public demand for change and that the revolutionary proposals emanate from a numerically insignificant, interested minority does not mean that there is no possibility of change occurring. Most unfortunately, in some respects, we are passing through such a tumultuous period of change in social concepts that legislative panaceas are advanced and accepted almost blindly without the consideration and the finer weighing of values that attend more normal times.

The proposals of change are so numerous and varied in type that only a few of the apparently more important can be discussed. This discussion, therefore, will be limited to a consideration of three general types of proposals or activities, contemplated or initiated: (1) compulsory health insurance; (2) legislation to permit corporations or other lay groups or individuals to engage in the practice of medicine; and (3) what for want of a better phrase may be termed invasion of the field of the private practice of medicine by governmental agencies.

Compulsory Health Insurance

Notwithstanding the agitation for compulsory health insurance by some students of the social welfare problem for the past twenty-five years or so, no state legislature was presented with a concrete proposal until after the Association for Social Security, Inc., Abraham Epstein, Secretary, brought forth late in 1934 a so-called model state bill for health insurance. This bill is believed to embody the general outline, at least, of any scheme for compulsory health insurance that will be pressed for consideration in state legislatures, for some time to come.

This bill, with certain minor amendments, was introduced but failed of enactment in 1935 in the legislatures of five states, in 1936 in two states, in 1937 in five states and the United States Senate, and so far in 1938 in three states.

Bills proposing systems of compulsory health insurance, founded largely on the Epstein philosophy but differing somewhat on details, were considered and killed in two states both in 1935 and 1937.

The so-called model health insurance bill in short proposes to create in each state a health insurance fund, to which all employees to whom the compulsory features of the bill apply, together with their employers and the state, would pay a total of 6 per cent of the wages paid and received. A person electing voluntarily to come under the act and the state would contribute a sum equal up to 6 per cent of the person's

*Read before the County Officers' meeting, Saint Paul, Minnesota, February 26, 1938.

income, the percentage varying according to the benefits desired. The fund thus created would be used to supply to the worker and his dependents all manner of medical, hospital, dental and nursing services and the services of specialists, laboratories and clinics for preventive, diagnostic and therapeutic care.

The bill also provides for other benefits, such as the payment of cash during disability, but these will not be here discussed.

The compulsory features of the bill apply to *all* employees *except* (1) persons employed at other than manual labor and receiving in excess of $60 a week in *wages;* (2) farm laborers, and (3) domestic servants. Almost any person whose net *income* is not over $100 weekly and who is not covered by the compulsory provisions may for himself and dependents elect to come under the Act. The medical benefits may also be available to persons receiving old age or unemployment benefits.

Estimates as to what percentage of the population all of the groups just enumerated would constitute run from 70 to 95 per cent.

Some reference must be made to the administrative set-up of the bill for it ignores organized medicine and would seem to leave the individual physician and even the medical profession in a most impotent position without any authority in the administration of the law and powerless against the dictates and encroachments of political caprice.

The supreme administrative authority is a State Health Insurance Commission of five members, only one of whom would be representative of what the bill designates as the "Professions" and this representative, appointed by a political governor, might as well within the terms of the bill be a nurse, a pharmacist, a dentist, a hospital manager, as a physician. Acting in only an advisory capacity to this commission are a State General Advisory Council and a State Medical Advisory Council, on neither of which is the medical profession afforded adequate representation.

The act would be administered in local areas through local councils consisting of seven members, one of whom would be a local medical manager (an M.D.), the local health officer, and one representative of "the professions." With the exception of the local health officer, all members of the local council are to be appointed by the lay-controlled State Health Insurance Commission.

A person entitled to medical benefits theoretically has the right to choose the general medical or dental practitioner he desires provided that practitioner is on a list of eligible practitioners compiled by the local council. The general practitioner chosen has the right to prescribe the specialist or laboratory or clinic services necessary for further treatment and the general practitioner or the specialist has the right to prescribe the necessary hospital treatment and nursing care, provided the persons or agencies selected are on the eligible list compiled by the local council. Every practitioner has the right to be included on such list. Names on the eligible list may be removed by the local council or by the State Health Insurance Commission, after written notice and hearing, "when in its operation continued inclusion in the list" would be prejudicial to the adequate, proper or efficient furnishing of the medical benefits." Whether the presence of this provision would prevent the arbitrary removal of a physician from the eligible list is debatable. A physician after a number of years of such practice and with a negligible private practice might well be at the mercy of political schemers.

The manner in which and extent to which persons and agencies on the eligible list would be recompensed could be fixed in each local area by the appropriate local council. In remunerating general medical and dental practitioners the local councils would be authorized to adopt either a salary system, a per capita system, a fee system, or any combination of the systems just enumerated. However, no system of remuneration could be inaugurated for any one local area unless a majority of the eligible general medical or dental practitioners, respectively, in that locality consented. This language means nothing, however, for it could be construed to mean a majority at the time the plan was adopted when a very few were on the eligible list and all subsequent additions would take subject to the existing plan.

The foregoing has been but a brief summary of such provisions of the Epstein bill as affect physicians. Without indulging in argument, it seems obvious that the long range effect of the enactment of such a measure would be to dilute and debase medical services to the public and

eventually to eliminate the high caliber and high purpose of an independent medical profession, leaving in its stead a group of practitioners, not physicians in any connotation the word bears today. Whether or not this bill or any one founded on a similar philosophy will ever become law in any state is debatable. Compulsory health insurance bills, however, will appear before legislatures for some time to come.

Practice of Medicine by Corporations and Other Lay Associations and Persons

Another threat to the quality of medical services has been legislative proposals, the effect of which would be to permit corporations and other lay associations and persons to exploit the services of physicians in the distribution of medical services to the public.

The past ten years have seen the rise of proposals ostensibly endeavoring to utilize the insurance principle in the distribution of medical services. Presumably so long as these proposals contemplate cash payments to the beneficiaries in the event of sickness or disability in order that they may themselves pay physicians they themselves have selected free from outside dictation the medical profession faces no apparent danger. However, when the proposal is for the insurance company or the medical service association, or whatever it may be called, to undertake, in case of sickness or disability, to supply the services of physicians of their own choosing, the situation is radically different.

Almost unnoticed, beginning in 1934, nine states have enacted laws authorizing the formation of corporations to operate on a so-called non-profit basis hospital service plans. Generally, these laws authorize such corporations to accept periodical premiums from subscribers and in the event the subscriber becomes sick or disabled to supply, either themselves or through hospitals with whom they have contracted, necessary hospital services. Some danger is inherent in such laws unless the term "hospital services" is limited to actual hospital services and the law as so limited enforced. In actual operation some of the plans authorized by these laws have infringed on the practice of medicine to varying degrees. Such laws have been enacted in New York, Alabama, California, Illinois, Maryland, Massachusetts, Mississippi, Georgia, and Pennsylvania. Similar bills were before the Minnesota legislature in 1937* but failed of enactment.

Bills which expanded on the theory by proposing to permit designated types of corporations and associations to operate hospital and medical service plans, were before six state legislatures in 1937.† None of them was enacted.

In some of our western states many plans similar to those just referred to have been in operation for years. The plans have been generally available only to workers in the employ of stated corporations, industries, or governmental agencies and not to the public generally. In some sections, medical societies have attempted to operate similar plans because of the presence of commercial ventures in the field. On the whole, however, with a few notable exceptions, it would seem that even where such plans are in operation, by commercial interests or by medical societies, the public has not patronized them in appreciable numbers.

One of the most widely publicized attempts of a corporation to offer medical, surgical and hospital services on an insurance basis is now occurring in Washington, D. C., in the activities of the Group Health Assn., Inc., which was the recipient of an outright gift of $40,000 from an agency of the Federal Government, the Home Owners Loan Corporation.

According to its certificate of incorporation, the corporation will render medical, surgical and hospital services to every subscribing employee and his dependents, of every branch of the United States government other than the personnel of the army and navy. It began the dispensing of medical care November 1, 1937, and by December 18, 1937, about 900 persons had subscribed to the plan.

Responsible officials of the Home Owners Loan Corporation say officially that a group of its employees organized the corporation and that the HOLC approved the scheme, believing that the HOLC would stand to benefit by reduced sick leaves if a complete so-called health service could be arranged for its employees on a basis of monthly pay deductions. Now as a matter of fact, the plan as it evolved embraced, if the articles of incorporation are any criterion, not only employees of HOLC but all other governmental agencies with the exceptions noted. And,

*S. 962, H. 1142.

†Calif. S. 121, A. 1283, S. 605, A. 1491; Ohio S. 204, H. 210; Oklahoma H. 335; Ore. H. 281, H. 283; Wash. H. 385, H. 386; Wis. A. 850.

as a matter of fact, the HOLC did considerably more than approve the plan. It coöperated, if actually it did not instigate the whole business, and without the aid of the HOLC it probably could not have come into being.

In March, 1937, shortly after the corporation was organized, the HOLC entered into a contract with the Group Health Association by which the HOLC agreed to give $40,000 spread over more than a two year period to the association and the association agreed to operate a medical service plan that would include employees of HOLC and would provide by-laws satisfactory to HOLC, which by-laws would provide that two of the association's directors be named by the Federal Home Loan Bank Board and that those two directors would be members of an executive committee of five of the association's directors. Rather active approval. Now while the association did not begin to dispense its medical care until November 1, 1937, all the $40,000 had been handed over to the association prior to that time. This haste was due probably, at least in part, to a premonition that the appropriate Congessional committee which would pass on appropriations to the HOLC might not feel favorable to diversions of public funds of that sort. And so it developed. The theory by which the HOLC sought to justify this diversion of public funds met strong criticism from members of the subcommittee of the Committee of Appropriations, House of Representatives, in a hearing held on December 18, 1937, on the Independent Offices Appropriation bill for 1939, when this whole matter was under discussion.

In any event, it would seem that the activities of GHA are illegal for two reasons: (1) they constitute the practice of medicine by a corporation, which the law forbids; and (2) they constitute the doing of an insurance business without complying with the laws of the District of Columbia which permit insurance companies to operate only when licensed by the Superintendent of Insurance after complying with certain requirements of law, among which is a requirement of a deposit of certain funds. This conclusion was reached by the corporation counsel and by the district attorney of the District of Columbia. Furthermore, the Acting Comptroller General of the United States, Richard N. Elliott, on December 17, 1937, ruled that the HOLC acted without authority of law in disbursing the $40,000 to the GHA.

There the matter now rests. Nevertheless the Group Health Association continues to operate in open defiance of law. Unless curbed, it can, if it expands to include all eligible persons, practically destroy the private practice of medicine in the District of Columbia. Whether it will do so and whether its activities will eventually encompass the United States, as they well can-are questions that only the future can answer.

Practice of Medicine by Governmental Agencies

A third, and possibly the most menacing, threat to the private practice of medicine are proposals for the governmental assumption of some or all of the functions of the practice of medicine and the rendering to some or all of its citizens necessary medical care free of charge or at such reduced rates as will preclude the coexistence of an independent body of medical practitioners.

In the past we have seen the development of state medicine to a limited extent. Probably the expansion of state health departments in the field of preventive medicine, and the care afforded mental incompetents, the tuberculous, and to some of the poor can be so classified. In many states, also, state or county general hospitals are in operation and there has been a constant effort to expand such facilities and to enlarge on the classes of population eligible for treatment therein.

Proposals put to the legislatures and the Congress in the last few years and the actions sought to be authorized by governmental agencies are continually going further and further into the field of the practice of medicine. Consider, for instance, the Lewis bill introduced in the U. S. Senate July 22, 1937,* which sought to make all physicians civil officers of the Federal Government, to require them to attend any "impoverished individual" on request and to authorize them to make such charges as "are just and reasonable," which charges were to be paid by the Social Security Board. That bill is still pending but is believed to have no chance whatsoever of enactment.

Reference should be made here to the rendition of the services contemplated by the Federal

*S. J. Res. 188.

Social Security Act, namely, care for crippled children, maternal and child health services, and state and public health services. Fortunately the services contemplated have been rendered to date in a most ethical manner, after consultation with and in accordance with the advice of the organized medical profession. But the possibility of abuse is always present so long as any portion of those services is subject to lay control. In this connection, too, vigilance must be unremitting in the enactment or enforcement of state laws designed to enable a State to avail itself of the federal subventions preferred in the Social Security Act. There have been isolated proposals—I believe one was pending before the Minnesota House in 1937—to permit a lay agency to supervise or administer the distribution of the medical services called for by the act.

The administration of medical aid to the clients of the Rural Resettlement Administration, now the Farm Security Administration, has aroused considerable comment. The practice varied from State to State. It almost seemed that in those States in which the state medical society was alert no objectionable practices were instituted and the plans that were put into operation were often the result of consultation with the medical society. Elsewhere attempts were made to care for the medical needs of the relief clients on a contract basis with individual physicians or groups of physicians. This, obviously, would deprive the patient of free choice of physician. In several States attempts were made to set up medical coöperatives which seemed objectionable because the terminology employed in the articles of incorporation of some of these coöperatives was so broad that (1) it would permit a much greater group of the inhabitants of the State in question than the relief clients to avail themselves of the medical care it offered and (2) it would enable the coöperative to *supply* the services of physicians rather than pay for them. Whether the coöperatives actually will do more than pay for medical services rendered FSA clients is a question for the future to determine.

In some states repeated efforts have been made to enact legislation to permit the admittance to various types of governmental hospitals of all persons needing medical care, regardless of indigency or non-indigency, on the payment of fees determined by the governing board.† The possible consequences of the enactment of such legislation are not hard to imagine. Within the very recent past in one county in a western State the county general hospital became a political football. Certain members of the board of county commissioners, which appointed the hospital board, stood for re-election on a platform of free medical and hospital services for all and a campaign of vituperation was conducted against the county medical society, which quite naturally opposed the scheme. The matter was eventually settled in the courts and the hospital board was enjoined from caring for others than indigents.

Bills have been considered recently in several States, which, if enacted, would have certainly socialized the practice of medicine and put it under governmental domination more complete than any proposal heretofore alluded to. Some of these bills contemplated nothing more or less than the creation of a separate department of state government to render free medical, dental and hospital care to all residents.* Two of the bills proposed† that all physicians in the State treat patients under the direction of the designated State department, each physician being paid a monthly salary based on the number of years he had been licensed. A bill recently considered in South Dakota‡ sought to authorize county commissioners to levy a tax sufficient to pay for necessary medical, surgical and hospital care for all residents of their counties. A resident was to be at liberty to choose any physician or hospital he desired and the county would pay the bill in accordance with a definite fee schedule which made none of the distinctions on which prevailing medical charges are made.

There is an increasing tendency to compel the state to arrange for and supply the necessary maintenance, medical and surgical treatment, and hospitalization for indigent expectant mothers. Such a law was enacted in Nevada in 1935 (c. 171) and was considered and killed in several states in 1937. Such a law is not objectionable, of course, if it provides free choice of physician, affords reasonable compensation to the physician chosen, and if its administration is limited to indigents.

Falling in the category of legislative proposals

†1937 Calif. SCA 5, A. 1196; Nev. A. 187; Idaho S. 169.

discussed in this paper are a series of bills introduced in the Wisconsin Assembly in 1937 by Assemblyman Andrew J. Biemiller of Milwaukee. One bill so introduced (661A) sought to create an interim committee "to investigate the general subject of medical care and the ways and means of lightening the burden thereof." Another bill (662A) sought to authorize the formation of non-profit corporations to operate group hospitalization plans. Another bill (740A) proposed to make it the duty of the county boards of supervisors in each county to provide "medical, dental and hospital services and treatment for all poor persons receiving relief in said county." Still another bill (747A) proposed to authorize the common council or board of any political subdivision to "subsidize wholly or partially a physician or physicians whenever there shall be an insufficient number of competent physicians in their respective communities." Such physicians were to "work under the direction and rules of the common council or boards affected." Another bill (850A) would have permitted the creation and operation of so-called medical coöperatives and proposed to prohibit medical societies from disciplining such of their members as supplied services to a coöperative and to forbid hospitals from discriminating in any way against physicians coöperating with such groups. Finally, one bill (852A) embraced a compulsory health insurance scheme based largely on the Epstein philosophy but which did not propose to confer anything but medical, dental and hospital benefits. None of these bills was enacted.

These, in brief, are a few of what may be termed preferred legislative solutions to the problems of medical care. Not one of them, it is submitted, even approaches a partial solution to that problem. No solution, it can be asserted confidently, will be found in any plan that in any way debases the medical profession, for the quality of medical services is of primary importance. The medical profession, it would seem, must fight not only to maintain its own independence, integrity, and high standards, but also to see to it that the public is not cajoled into accepting a form of medical practice that in destroying an independent and capable profession will leave in its place an incompetent group of servile practitioners bringing with them a retrogression in medical progress and medical care. The American public must not be placed in the situation Æsop depicts in the fable of the dog which dropped his bone for a seemingly larger and more delectable one reflected in the water below him.

FOOD SENSITIVITY SIMULATING GASTRO-INTESTINAL DISEASE*

CLEMENT I. KRANTZ, M.D.
Duluth, Minnesota

DURING the past several years the medical profession and even to some degree the lay public have become conscious of the fact that food idiosyncrasies may be at the basis of some of the ill defined, indefinite symptoms referable to the gastro-intestinal tract. Great advances have been made in the field of allergy, since the observations on anaphylaxis by Richet of France. The proof that hay fever was caused by the protein fraction of pollen soon followed and, in the natural course of investigation, the food proteins came in for consideration so that the cause for many obscure cases of food poisoning was now found. Under the leadership of Coca, Duke, Rackemann, Vaughan, and many others, the treatment of these cases of allergy was soon started, so that today the sufferer may in a large percentage of cases acquire some and even complete relief from his distressing symptoms.

The diagnosis of food sensitivity is not always easy. Perhaps the earliest and certainly one of the most reliable tests has been the patient's own experience with the production of symptoms on eating the offending food. This has been most apparent in those cases where eruptions on the body or urticaria have resulted after the ingestion of, or contact with, the material at fault. However, when asthma, eczema, or similar allergic manifestations are present, it is rare that the individual himself recognizes the importance of foods as the causative factor. Moreover, this is even more true in cases where

*Read before the Northern Minnesota Medical Association at Virginia, Minnesota, August 27, 1937.

foodstuffs have been found to be the offending material in the production of gastro-intestinal symptoms and so often the symptoms are ascribed to other, non-allergic, often vague diseases of the digestive apparatus.

The value of the scratch and intradermal tests in searching for the cause of the underlying sensitivity is at present open to some question. Care should be used in their interpretation, because a positive reaction may not mean clinical allergy and, by the same token, a negative test may be present when the offending material may produce clinical symptoms. Alexander[1] and Vaughan[11] have thrown some light on this subject and state that the gastro-intestinal tract, bronchi, or other reacting tissues of the body may alone contain reagins, whereas the skin may contain none, and hence negative tests result. Furthemore, the age of the patient and the technic of testing as well as the site of the application may cause variations in the test.

The skin test, however, should not be disregarded, for in some instances at least, it may give a lead to further study. The trial by diet, the so-called elimination diet, has assumed a greater importance in the diagnosis of this problem. Rowe[8, 9] in several reports has gone into detail discussing its value, which has since been corroborated by many writers. There are further means of diagnosis, namely the passive transfer test, and the leukopenic index as presented by Vaughan.[12] The latter test is of definite value in some cases[7, 10, 12, 13] though the results must be interpreted with caution.[5]

In the present report, a study has been made of individuals giving evidence of food allergy with symptoms referred to the gastro-intestinal tract. Many of these cases had been previously studied and treatment instituted, often without relief. These symptoms were such as to simulate other conditions, viz., duodenal ulcer, gallbladder disease, acute gastro-intestinal disturbances, spastic or irritable colon, etc. For convenience in illustrating these symptoms, the following case reports are presented:

Cases Simulating Upper Gastro-Intestinal Disease

Case 1.—J. B., male, aged forty-five years. His chief complaint was discomfort in his abdomen, particularly a few hours after meals. In 1927, he was informed that he had a duodenal ulcer, though several roentgen-ray studies failed to reveal any ulceration of the upper gastro-intestinal tract. His diet was varied, though he had abstained from fatty foods. Vegetables caused no discomfort, but highly seasoned foods did. The principal foods were quantities of milk, eggs, beef, and bread. The usual powdered medication used in the treatment of ulcer gave no relief from symptoms.

For many years past he had had mild attacks of hay fever and there was a history of allergic disease in his family.

The physical examination was essentially negative except for moderate tenderness upon palpation of the epigastrium.

Scratch and intradermal tests were given and showed markedly positive reactions to milk and eggs and a two plus reaction to beef and black pepper. The articles were then eliminated from his diet with complete relief of symptoms. When eggs and milk were again restored to the diet, the symptoms of abdominal distress returned, and since then these have been entirely withdrawn from his food intake.

Case 2.—Mrs. F. H., female, aged thirty-six years, complained of an acute onset of nausea, vomiting and acute upper abdominal distress, which she believed resulted from taking a small amount of fermented liquor the evening previous. Further investigation revealed that she had never taken milk or eggs except mixed with other cooked foods, but that during the past few days she had taken a glass of milk each evening.

In the past she had had several spells of less severity on rare occasions. There was no history of allergic disease in her family.

Physical examination revealed nothing except some abdominal distention. Intradermal tests were made with extracts of various foods and a three plus reaction to milk and a two plus to eggs resulted. These substances were accordingly eliminated from her diet.

She recovered promptly from her illness and found also that fermented liquor did not cause return of any symptom. On one occasion she was ordered to take milk with her diet and then had a return of epigastric discomfort. Since avoiding these food materials she has since been free from any gastro-intestinal symptoms.

Case 3.—Mrs. A. H., aged thirty years. The chief complaint was vomiting, epigastric discomfort and headaches of the migraine type, which would disable her for three days at a time every few weeks. These had been present for years, and the headaches relieved only temporarily by medication. There was no history of allergic disease in the family, but her mother had suffered from headaches.

The physical examination was entirely negative. Elimination diets were tried after intradermal tests had shown a markedly positive test for milk, and lesser reactions (two plus) to bananas, cabbage, and black pepper. Milk elimination stopped the above mentioned symptoms. An oral desensitization diet for milk ac-

cording to Kesten and Hopkins[4] was tried, but when this was half completed, she had a return of headaches and gastro-intestinal distress. Complete elimination of milk alleviated all symptoms.

In January, 1937, she was delivered of a child, which she began to nurse. Headaches and nausea of milder degree returned, lasting only one day. She last reported that these seemed to lessen slightly, but it is probable that they will not be completely eliminated until she has stopped nursing her child.

Cases Simulating Acute or Chronic Disease of the Colon

Case 4.—Miss E. C., female, aged twenty-five years. Her chief complaint was pain in the right and mid-epigastrium, alternating spells of diarrhea and constipation. She had been chronically ill for many years. In 1932 a retrocecal appendix was removed and in 1935 a gallbladder without stones but with a few adhesions was taken out. Symptoms still persisted despite the many varied forms of medication given. There was no family history of allergic disease.

Examination showed a somewhat undernourished young woman. There was tenderness on pressure in the right epigastrium and along the descending colon on the left side. Roentgen-ray films revealed a moderate degree of visceroptosis and a spastic colon.

Scratch and intradermal tests showed a positive reaction to many foods, particularly tomato, pork, and carrots (three plus). The reaction to milk was only one plus. Beacuse of the severity of the symptoms, elimination diets were tried. Among the first foods eliminated was milk. During this period, the symptoms of pain in the epigastrium were greatly alleviated and the bowel function returned to normal. However, because she was not gaining in weight, goat's milk was added to her food intake. For a period of two months she was fairly comfortable, but in June, 1936, diarrhea again set in with fifteen to twenty movements per day. Hospital treatment was instituted and goat's milk was removed from the diet. The diarrhea subsided within a few days and since then she has not been troubled in this way. Tomatoes and citrus fruits caused return of epigastric distress, but elimination of these alleviated the symptoms to a great degree. Soy bean milk has been used to replace milk and she has regained six pounds in weight. At present she is comfortable unless she experiences mental strain, when a mild diarrhea sets in for a few days.

Case 5.—Mrs. R. MacG., aged thirty-one years. For years this patient had been troubled with gastro-intestinal distress and she stated she had to be "fussy" with her diet. She had spells of what she called colitis, with pain particularly over the descending colon. In 1934 symptoms of pain in the pelvis were complained of and examination revealed a mass in the left culdesac. At operation endometrial tumors were found and removed and a chronically inflamed appendix was taken out. However, she still complained of food difficulties and roentgen-ray studies revealed a spastic colon. She did not receive much relief from treatment.

In May, 1937, she complained of discomfort after eating, stating that she believed her trouble was due to poisoning from food stuffs. She always felt tired and at times had much distention of her abdomen. At these times palpitation of her heart would set in and the pulse rate increase to 140 or 150 beats per minute. Her stools were watery and loose, but sometimes stringy with much mucus. She believed meat and eggs caused most of her trouble.

Examination was negative except for tenderness in the epigastrium and left flank of the abdomen. Scratch and intradermal tests revealed a three plus reaction to milk, two plus to wheat, rye and white potatoes. These were removed from her diet with complete relief of symptoms. Oral desensitization diets were given and after a few months she was able to eat small amounts of bread without discomfort. She has never been able to partake of milk without return of symptoms.

Discussion

The symptoms presented by these patients are common in many non-allergic diseases of the gastro-intestinal tract. In determining the underlying etiological factor causing these complaints, careful attention to the history is essential. Often there is a history of hay fever, as in Case 1; or a familial history of allergic disease may be obtained, which will give a clue to the diagnosis. A careful evaluation of the diet list may reveal some new food recently added to the list and may be the material at fault as in Case 2. Moreover, it is not uncommon for these sufferers to have widely varied medical treatment, even undergoing operation without relief of symptoms. In cases suggestive of ulcer or cholecystic disease, the absence of positive roentgen-ray findings may be the determining factor in stimulating the physician to resort to the study of possible allergic factors.

The dislike for foods very often has no relation to the allergic food factor at fault and even the patient's own statement that certain foods are disliked or cause distress may or may not contribute to finding the cause, as in Case 2. So often the offending food comes as a complete surprise not only to the patient himself, but also to the physician. The foods that are most commonly used, such as milk, eggs, wheat, or tomatoes, are most often the causative factors in a series of cases studied. Alvarez[2, 3] has discussed this problem at length with a careful analysis of symptoms and their

relation to food sensitivity and has come to the same conclusions.

These selected cases also show that too much reliance should not be placed on one method of diagnosis alone, but that the elimination diet or diary diet of Alvarez should be resorted to in these individuals. This is well illustrated in Case 4 where the intradermal test was only very slightly positive, but there was clinical evidence of severe sensitivity to milk as proven by the test diets. Here the gastro-intestinal tract was the shock organ, so to speak, and the skin showed only slight sensitivity. Thus it is evident that the patient should be given the benefit of the test diets, for with those sensitive to many food stuffs, the diet list may be cut down too much for the patient's own welfare, even to the extent of making his food intake lack both in the amounts and kinds of food material necessary for well-being.

Patients 3 and 4 present an interesting study in antigenically related substances, in this case milk. Ratner[6] has studied this problem and suggests that milk derived from the various species of animals may be antigenically related. In patient 3, there is a probability that the symptoms of nausea, vomiting, and migraine headaches may be due to her own milk. Patient 4 did well after the removal of cow's milk from her diet. However, she used goat's milk for two months and then severe gastro-intestinal symptoms appeared. They were relieved only by removal of this article of food from her diet. In this case we can assume that there was a relation between cow's and goat's milk to produce allergic symptoms.

Summary and Conclusions

1. Case reports have been presented to illustrate that food sensitivity may often simulate organic gastro-intestinal disease.

2. Too much reliance should not be placed on a single method of diagnosis, such as the scratch test, but a careful history of previous allergic disease should be obtained and then the elimination or diary diets together with other methods of diagnosis should be used.

3. This is even more necessary in those individuals positive to many substances by the scratch test, because too limited a diet may deprive the patient of food elements necessary to the proper sustenance of life and well-being.

THE DANGERS OF LATE DIAGNOSIS OF INTESTINAL DISEASES*

J. ARNOLD BARGEN, M.D.

Rochester, Minnesota

SOME of the most serious lesions of the human body are found in the large intestine. Their early diagnosis, therefore, is imperative. It is my purpose in this paper to call attention to some of the more common symptoms, signs, and methods of early diagnosis of intestinal disorders.

Any change in bowel function should suggest the possibility of intestinal disease. Sometimes such a change may be very slight, for when one considers the nature and contour of the large intestine, a lesion may grow to considerable dimensions before it produces a change in the intestinal habits. In an individual whose bowel movements have always occurred at a regular time of day, therefore, any irregularity in going to stool may be an early symptom of intrinsic disease. Another common early complaint is

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the Northern Minnesota Medical Association, Virginia, Minnesota, August 27-28, 1937.

fragmentation of the stools, and where formerly an individual may have had one normal, formed stool, he may suddenly have three or four small ones, and he may not seem to be able to empty his bowel completely except after repeated small passages.

Gaseous dyspepsia and bloating are common complaints, and indefinite abdominal discomfort, which may or may not follow the line of the large intestine, occurs frequently. The passage of intestinal mucus may or may not signify a lesion in the intestine. Without doubt much too much attention has been paid to mucous discharge from the rectum. Too often it has been called evidence of colitis without a thorough investigation. More often than not it is simply the result of a type of systemic irritation in which the intestine is affected reflexly. However, it is not possible to establish this fact without proper objective investigation. Hence, when unnatural quantities of mucus are passed, a thorough study of the intestine should be made to establish the possibility of an early organic lesion. The passage of pus is indicative of some type of inflammatory disease.

Blood in the stools should always be considered of serious moment until proved otherwise. It is easy to blame the passage of blood in the stools on the presence of hemorrhoids. It is much safer to consider the presence of blood as due to a neoplastic lesion until proof to the contrary is available.

The development of constipation in an individual who has otherwise had normal bowel function should also be considered of significance. Constipation, of course, is more often due to functional disorders than to actual organic disease, but one should never be satisfied to say that the constipation is of a functional nature unless every effort has been made to prove the contrary. Unexplained loss of weight may be associated with early intestinal disease. The pallor seen in individuals with slowly progressing anemia is rather characteristic, particularly in cases in which the lesion is in the right half of the colon. Then, too, among patients who have had chronic ulcerative colitis (colitis gravis) for some time there develops a peculiar pallor which was originally described by Logan as that of "visceral degeneration." Innumerable nervous disturbances may also be associated with intestinal disorders, often to the point of depression, and the old saying of Osler that "disease above the diaphragm makes for optimism and that below the diaphragm for pessimism" well expresses the situation. These and many other symptoms may be taken as early expressions of intrinsic intestinal disease.

When satisfied that a patient's complaints point to a disturbed function of the intestine, a very careful physical examination should be made, and this in detail often gives valuable information. Probably the most important part of the physical examination is a careful examination of the rectum. A general examination of the chest and abdomen often gives valuable and sometimes unexpected information. A well-planned and well-ordered set of objective tests, including examination of the stools, x-ray studies of the large intestine, and the direct inspection of the bowel lining through the proctoscope, has the greatest value.

If this plan of study is followed, many of the serious lesions found in the intestine will be diagnosed early and at a time when their complete eradication is possible.

Vitamin D Milk Produced by Feeding Cows Irradiated Yeast

In 1929 Wachtel reported that the feeding of irradiated dried yeast to cows resulted in the secretion of vitamin D in the milk. This report was confirmed and amplified by the observations of Hart and Steenbock and their associates at the University of Wisconsin. Since 1932 this type of vitamin D milk has been made commercially available. The product is sometimes referred to as "metabolized" vitamin D milk. Numerous investigators have reported on the clinical effectiveness of metabolized vitamin D milk. These investigators have shown that, if there is any difference, unit for unit, between different types of vitamin D milk, the difference is too small to be of practical significance. Metabolized vitamin D milk is produced under the joint sponsorship of Standard Brands, Incorporated, and the Wisconsin Alumni Research Foundation. The irradiated dried yeast intended for use in the feeding of cows may be sold by Standard Brands, Incorporated, only to dairymen licensed by the Wisconsin Alumni Research Foundation. The vitamin D content of the milk produced, as shown by repeated bioassays, is not less than 400 units of vitamin D per quart. The Council on Foods voted to accept pasteurized metabolized vitamin D milk and to grant the use of the seal of acceptance to licensed dairies that conform to the Rules and Decision of the Council. (Jour. A.M.A., Nov. 27, 1937, p. 1814.)

COMPARATIVE VALUES OF INJECTION AND SURGICAL TREATMENT OF HERNIA*

GEORGE EARL, M.D.
Saint Paul, Minnesota

PREVIOUS to the last decade, injections for the cure of hernia attracted little attention. The solutions of Pina Maestræ of Spain were handled with great secrecy and in this country sold at such high prices that they had been little used. Mayer of Detroit was using the injection method long before he gave medical publicity to it. Bratrud of Minneapolis, together with McKiney, Rice, and Larson, deserve credit for taking the matter up in a clinical teaching way and giving the profession solutions, methods, and the results of their experience.

It is estimated that 10 per cent of the population have herniæ in some form or other. The majority, influenced by economic considerations, necessity of hospitalization, objections to surgery and recurrences after operation, prefer to wear trusses. The tendency now is for active treatment to be sought earlier.

Inguinal hernia comprises most of the cases selected for injection because trusses are fitted more easily, and, anatomically, the injections are simpler. The direct inguinal type gives more difficulty than the indirect because of gravity and also because the structures of the internal and external oblique muscles are often frayed out or almost absent. Evidences of this are the many surgical devices used, such as fascia lata strips from the thigh, turning down of fascia from the rectus muscle or incision of the fascia of the internal oblique near its attachment to the rectus muscle so as to free the internal oblique for approximation to Poupart's ligament. Direct hernia becomes more frequent in later life. Age presents poorer reacting qualities, hernia of longer duration, degenerative changes, often increased fat, and the protruding abdomen placing the inguinal hernia more at the bottom of a sack. The number of injections needed increases with each decade of life, and many more are usually needed with direct than with indirect inguinal hernia. The same factors necessitate more careful surgical procedure with direct hernia.

Is injection likely to damage the spermatic cord or the circulation of the testicle? Before any treatment, surgical or injection, the status of the cord and testicles should be carefully noted. Variation in size may be developmental or due to illness, such as mumps, or it may follow operations. I am injecting a dentist who suffered marked testicular atrophy following an operation and, with hernial occurrence on the other side, he has selected the injection method. The spermatic cord is very resistant to any needle implantation. The younger the individual, the more resistant the elements of the cord are. The thickness of the wall of the cord on section is many times greater than the lumen. Records of potency, semen examinations, findings at such operations as may be necessary following failure of the injection method, and post-mortem examinations in operated and injected individuals will ultimately determine comparative risks.

Femoral hernia, if reducible, may lend itself to injections. Femoral hernia occurs jointly with inguinal hernia more frequently than is usually suspected. Sometimes it is not noticeable until the inguinal hernia has been corrected by operation or injection.

Umbilical hernia, if small and free from any abdominal contents, may be treated by injections.

Post-incisional abdominal hernia, if small, may occasionally be closed by injections. One difficulty is that often this type of hernia may have multiple points of weakness. In the upper abdomen, because of the presence of the mesentery and liver, there is less chance of the development of bowel adhesions and hence injections are safer above the navel than below. Unless very minute and treated early, post-incisional rectus muscle and midline herniæ below the navel are positively surgical.

Recurrences in inguinal hernia following operation often lend themselves to control from injections. Previous operation has rearranged the tissues so that injections may fill in weak spots more readily.

Before injections are made, a satisfactory truss must be fitted. No one type fits every kind of hernia. A spring bar is most efficient in the in-

*Read before the Northern Minnesota Medical Association, Virginia, Minnesota, August 27, 1937.

guinal type. In umbilical and incisional hernia, trusses with attachments encircling the body are used. The truss may have to be adjusted repeatedly. The surgeon should fit and closely observe the truss. The truss must function positively to hold the hernia. For the discomfort and chafing present at times, a buffer cloth between the truss and skin is helpful. Toughening of the skin with alcohol and dusting powder is useful. The truss is worn night and day to begin with and preferably so during the injection period. After apparent cure, it should still be worn two to six months longer, depending upon the type of hernia and the difficulty in securing healing. Then it is left off at night only and later during the day unless special strain or activities are undertaken.

Next comes the choice of the irritant to produce a foreign body granuloma—microscopically, a proliferation of endothelial and connective tissue cells forming scar tissue. Many solutions are being used, and this fact in itself is evidence of the still unsettled question as to which solution is best. Of the many in use, I have had experience with five.

1. *Thuja Mixture*

Phenol, 50 parts.
Alcohol, 25 parts.
Lloyds Specific Tincture of Thuja, 25 parts.
Allow to stand two days and then either decant or filter.

Except for a half dose at the internal ring, an average of eight minims is injected at each treatment. A tuberculin syringe is used. With such a small quantity of solution only a small area is affected, necessitating a greater number of injections. The Thuja mixture is its own sterilizing agent and needs no preliminary novocain for anesthesia.

2. *Mayer Formula*

Zinc Sulphate, 1 dram.
Glycerin, 4 fluid drams.
Fluid Extract Pinus Canadensis (dark), 5 fluid drams.
Phenol Crystals, 6 drams.
Aqua Cinnamomi, 1 fluid dram.
Sterlized chemically pure redistilled water, 2 fluid ounces.

The solution must be brought to boil each time before it is used. The average dose is eight minims.

3. *Bratrud Formula*

Tannic Acid 0.50
Benzyl Alcohol 3.00
Thymol 0.50
Alcohol (95%) 100.0

This product is suggested by Dr. A. Bratrud of Minneapolis. The tannic acid may be increased to 1 per cent in selected cases. Its advantage is that a larger amount can be used, probably on the average of 2 c.c. It is preceded by 1 c.c. of 2 per cent novocain. Bratrud adds two minims of Thuja mixture. All solutions are given through the same needle with change of syringes. The larger amount of solution gives a reaction over a larger area.

4. *Sodium Morrhuate*

This solution was suggested by Dr. D. D. Turnacliff of Minneapolis. I have used 2 c.c. of the solution preceded by 2 c.c. of 2 per cent novocain and followed by 1 c.c. of novocain. I have limited its use to the above dosage in difficult cases in which other solutions had previously been used. In my experience, with the dose mentioned, it gave the most marked reaction of all and therefore should be used with caution. I have seen no other reports regarding its use.

5. *Sodium Psylliate*

Of late I have used a sodium psylliate preparation. It causes no damage if spilled on the skin, the reactions are certainly less marked and, experimentally on animals, the reaction even on the peritoneum is reported mild. In cases which are difficult to close, I am inclined to return more frequently to solutions of greater reaction, such as Bratrud's formula, sodium morrhuate, or Thuja mixture.

For injection of an inguinal hernia, the patient is placed on a table with the hips elevated. Alcohol (70 per cent) is applied to the skin area. The approach to the region of weakness is through skin, fat, and fascia. The resistance of the fascia is definite. When the needle is passed through the fascia, freedom of motion of the needle is evident. An attempt should always be made to withdraw the piston of the syringe, to insure avoidance of vessels. The patient's reaction to pain also guides in the placement of the needle. The injection should be immediately stopped with any unusual reaction. It should be

given slowly. Repeated injections are placed in various areas of the inguinal canal according to the reaction obtained and points of greatest weakness. The nearer the internal ring, the more need for caution.

The frequency of injection depends upon the reaction, upon the number of areas needing injection and, to some degree, upon the convenience of the patient, particularly an out-of-town patient. The injections range from daily to weekly injection, usually allowing a week to elapse between injection of each area. Reaction in the form of swelling is encountered. I have seen none that has not subsided. I have not encountered infection.

In umbilical hernia, the defect is approached from all sides, dosage at any point being from one-quarter to one-eighth of that used in inguinal hernia. The peritoneum should not be penetrated. In femoral hernia, the dosage is about one-quarter and the approach is made with great care. Incisional herniæ, except in the inguinal region, are approached with much caution.

There are many interesting reports in literature. Pina Maestrae of Spain reports favorably on 8,000 cases.

Mayer of Detroit states that in his work a census of 2,100 cases of inguinal, femoral and umbilical hernia by subcutaneous injection showed complete relief without recurrence after a period of years in 98 per cent of the cases. Furthermore, more than 200 cases of hernia recurring after operation were subsequently completely relieved by the subcutaneous injection method.

Bratrud and McKinney at the University of Minnesota Hospital, and Rice and Larson at the Minneapolis General Hospital have given favorable reports on large series. This work at the University of Minnesota is especially to be commended because of the spirit of open-mindedness shown, and also because of the scientific approach and willingness to teach. Samuel W. Fowler of New York City has recently reported several hundred cases. Total reports now from all sources are large.

During the years 1933 and 1934 in a private practice trial, I operated upon thirty-eight patients and injected forty-two. Since then over two years have elapsed. Patients treated since 1934 are too recent for evaluation. Of the injection cases, thirty-seven were inguinal hernia, two were incisional, one umbilical, and two femoral. Of the thirty-seven inguinal, four had, in addition, femoral ring impulse; hence, both areas were injected. Two of the inguinal group had marked hydroceles which were treated also. Three of the injected cases were surgical recurrences, one of which had had three operations, and another two operations. These operated cases reacted well as the operations had left smaller areas of weakness for closure.

Of the operated patients, two had undescended testicles, two had marked testicle atrophy from mumps (one unilateral and one bilateral), five had femoral herniæ and six had post-incisional herniæ. The remaining twenty-three of the surgical group were inguinal herniæ.

Certain difficulties were encountered.

1. Severe enough reactions to cause the patient to lay off from work. The first was a laborer doing exceptionally heavy lifting and to whom I gave the largest dose of sodium morrhuate I ever used at one injection. He had the most marked reaction of my series. His lay-off lasted one week. He had a closure of the hernia following the severe reaction and has since referred a patient to me. The second was an older man who complained much of the character of his work. Besides compensation, he had other sources of insurance income and had it not been for the character of his work and also for his insurance, I feel that he would not have laid off at various times for a total of several weeks. Three other patients laid off, missing part or all of a day from work. Since using sodium psylliate, none has laid off from work. Reactions have been much reduced, but I am of the opinion that more injections are required than with the other solutions.

2. The most difficult herniæ to close were in four patients, all old men with long standing, large, direct herniæ. Two I have operated upon after prolonged injections. Adhesions were marked from the injections, but operation was not more difficult than expected. One of the two tired of injections and suggested operation himself. Another I apparently closed with forty-four injections but the hernia reopened. I have advised operation, which he may accept, although he still comes for injections. Another

has had thirty-nine injections and progress is very slow. He comes occasionally for injections. The advice I would give generally for hernia of this type is plastic repair. Others of this type, which apparently closed, will have to be injected again from time to time for recurrences or they may come to operation by me or drift into other hands, if they have not already done so. Observance for recurrence should be repeated regularly. Extra injections after apparent closure are necessary to improve results.

3. Swelling in the tissues accompanying the cord does occur at times with all the solutions mentioned except sodium psylliate. It has always subsided, however, in my experience. Twice I removed fluid from the center of the reacting mass. Patients become somewhat disturbed over such swellings and must be reassured.

4. Pain results from proximity to the nerves or to the peritoneum. In such cases the needle must be reinserted.

5. Influx of blood with a preliminary withdrawal of the piston, previous to injection, has occurred several times. The needle was promptly withdrawn and no complications followed. If the withdrawal had not been made promptly, trouble might have followed.

6. With patients who are unusually temperamental and highly sensitive to any manipulations, bromides or phenobarbital reduce the sensitiveness.

7. Difficulties with operation due to adhesions following injections. I have operated on two patients whom I myself have injected. Further, I have operated upon two others who had been treated elsewhere. Recently I removed an acute appendix in a patient who had had injections previously by a very competent man. I found the cecum markedly adherent, which made the operation for an acute, beginning gangrenous appendix located postcecally most difficult. Of course, at times, we find marked adhesions of the cecum without the patient ever having had injections, but in this case the adhesions were directly in line where the injections had been placed. Unquestionably, patients whom I have injected will have some adhesions which will come to light at operation or postmortem.

The cases reported on were injections begun in 1933 and 1934, and during those years, taking in all types of herniæ, I injected a few more than I operated upon, the ratio having been surgical 47.5 per cent, and injection 52.5 per cent. Of the cases of hernia I have seen in 1935, 1936, and 1937 and have not reported because they are too recent to evaluate, I have operated upon more than I have injected, the ratio being surgical 57 per cent and injection 43 per cent—a distinct shift toward surgery. Just where the pendulum between surgery and injections will come to rest will probably depend upon the individual surgeon. Some surgeons will operate only, others will tend toward injection. The majority of surgeons will probably do both injection and operation, depending upon the indications, upon the surgeon's inclination and experience, and somewhat upon the patient's economic circumstances and acceptance of, or objection to, surgery. A factor to be considered is that in the future patients with herniæ will come earlier for treatment due to compensation insurance, better health education, and the interest aroused by the chemical injection method.

Conclusion

Herniæ to be injected must be reducible and satisfactorily held in position with a truss. The large percentage of injections will be made in inguinal hernia, a few in femoral and umbilical. Only the smallest postoperative abdominal herniæ above the umbilicus lend themselves to the injection treatment. Below the navel the small bowel is more commonly directly adjacent to the peritoneum. If surgical recurrences are found early enough, the injection method may prevent reoperation, particularly in inguinal hernia.

Of the solutions used in my experience, sodium psylliate has been less accompanied by pain and swelling. Proliferal and sodium morrhuate produce greater reaction but, in spite of that, may be indicated. Thuja mixture and Mayer formula are useful at times. Other solutions with which I have had no experience may have equal or greater merit. Study of injection material will be continued and widened.

Because many injections are being given to older men who are succumbing to the degenerative diseases, postmortems should be increasingly available. Study should be made of the question

of semen and potency in patients operated and in those injected. The grouping of complications from either operation or injection should be increasingly recorded.

More accurate observation of the condition of the testicle and cord, previous both to operation and injection, should be recorded. It is natural that great interest should be aroused with any change in these organs, but too often an unfair and unjustifiable attitude of complaint is taken and hence every precaution is needed to record previous abnormalities.

Precautions always to be remembered are: Complete replacement of protruding tissues, which should positively be held in place with truss; withdrawal of the piston of the syringe to avoid injecting into a blood vessel; slow injection to try out the location and patient's reaction; careful follow-up and extra injections to secure sufficient strength in the holding tissues.

In selecting cases and advising patients concerning results with either operation or injection, ease of cure is in proportion to the decade of life, size and character of the hernia, general condition of patient's health, patient's coöperation, and the doctor's interest, knowledge, and experience in the procedure. A simple, indirect inguinal hernia is relatively easy of closure by the chemical injection method. All other types of hernia deserve careful study before treatment, other than operation, is advised. In the aged or decrepit, injections may bring relief without cure.

A qualified enthusiasm for the injection method will, of course, secure better results than half-hearted interest and less experience. To secure results with the injection method takes more persistence, close attention to detail and study of the individual case than some are willing to give when operation offers satisfactory results.

Because of recurrences and realizing that, after all, only scar tissue is secured from injections and this tends to give way, and because of the other difficulties discussed, I tend increasingly to advise operation more often than when first I began the trial of the injection method of treatment.

THE PRESENT STATUS OF INFESTATION OF FISHES OF LONG LAKE, ELY, MINNESOTA, WITH THE LARVAE OF DIPHYLLOBOTHRIUM LATUM*

HIRAM E. ESSEX, Ph.D.
Rochester, Minnesota

IN previous papers[1,2] it has been shown that susceptible fishes of Long Lake, also known as Shagawa Lake, at Ely, Minnesota, were more heavily infested with the plerocercoid larvæ of Diphyllobothrium latum than were fishes of any other body of water studied in this state. During the past summer (July, 1937) another series of fishes was examined to determine whether any changes in the incidence of infestation had occurred. The number and species of fishes examined were as follows: fifteen Stizostedion vitreum (walleyed pike); four Esox lucius (pickerel); two Perca flavescens (yellow perch). Both the musculature and viscera were inspected. The walleyed pike measured from 21.2 to 28.8 cm. in length and harbored from one to twenty-six larvæ. The average infestation was more than six larvæ for each fish. The pickerel varied from 38.7 to 45 cm. in length and each harbored from four to twenty-six larvæ. The average number of larvæ for each fish was more than fifteen. The two small yellow perch examined were not infested (Table I). The number of larvæ found in the different species of fishes examined prior to 1930 was approximately the same as found in the present survey (Table II). These data indicate very clearly that there has not been a change in the infestation of fishes of Long Lake, at Ely, Minnesota, since the previous investigations.

I wish to thank Dr. T. Surber for his cooperation and Wardens Hanson and Carlson for valuable assistance in obtaining fish for examination and Dr. J. E. Thompson for the use of his laboratories. I wish also to express appreciation to Donald C. Balfour, Jr., who assisted in all phases of the investigation.

*From the Division of Experimental Medicine, The Mayo Foundation, Rochester, Minnesota.

TABLE I. THE INFESTATION OF FISHES OF LONG LAKE WITH LARVÆ OF DIPHYLLOBOTHRIUM LATUM IN 1937

Species	Common Name	Length, cm.	Diphyllobothrium latum larvae
1. Stizostedion vitreum	Walleyed pike	25.6	7
2. Stizostedion vitreum	Walleyed pike	25.6	10
3. Stizostedion vitreum	Walleyed pike	28.1	2
4. Stizostedion vitreum	Walleyed pike	26.9	10
5. Stizostedion vitreum	Walleyed pike	27.5	4
6. Stizostedion vitreum	Walleyed pike	25.0	2
7. Stizostedion vitreum	Walleyed pike	28.1	4
8. Stizostedion vitreum	Walleyed pike	38.0	26
9. Stizostedion vitreum	Walleyed pike	21.25	4
10. Stizostedion vitreum	Walleyed pike	37.5	6
11. Stizostedion vitreum	Walleyed pike	28.8	4
12. Stizostedion vitreum	Walleyed pike	28.8	1
13. Stizostedion vitreum	Walleyed pike	28.1	5
14. Stizostedion vitreum	Walleyed pike	26.2	4
15. Stizostedion vitreum	Walleyed pike	23.1	3
1. Esox lucius	Pickerel	45.0	4
2. Esox lucius	Pickerel	43.1	17
3. Esox lucius	Pickerel	46.2	26
4. Esox lucius	Pickerel	38.7	16
1. Perca flavescens	Yellow perch	12.5	0
2. Perca flavescens	Yellow perch	15.0	0

TABLE II. THE INFESTATION OF FISHES WITH LARVÆ OF DIPHYLLOBOTHRIUM LATUM PRIOR TO 1930 COMPARED WITH INFESTATION IN 1937

	Prior to 1930		1937	
Species	Examined	Positive	Examined	Positive
Esox lucius	12	12	4	4
Stizostedion vitreum	6	6	15	15
Perca flavescens	10	6	2	0
Total	28	24	21	19

OVARIAN TUMORS AMONG YOUNG GIRLS

CHARLES W. MAYO,† M.D., and WINFIELD L. BUTSCH,‡ M.D.

Rochester, Minnesota

WHILE comparatively rare, ovarian tumors occur with sufficient frequency among young girls to make it essential to keep the possibility in mind when dealing with abdominal symptoms. The diagnosis can be made preoperatively in most instances.

Mayo and Fauster, in 1932, reviewed the cases in which ovarian tumors were found among young girls at The Mayo Clinic. This report deals with the subsequent cases in which this condition was encountered. Hubert recorded 175 cases in which solid and cystic tumors of the ovary were found among children up to seventeen years of age. Of these, sixty were malignant and 115 benign. Of the malignant tumors, thirty-two were sarcomas and twenty-eight were carcinomas. Of the benign tumors, fifty-three were cysts, thirty-nine were dermoids, nineteen were cystadenomas and four were hematomas.

This clearly brings to mind the serious import of the diagnosis of an ovarian tumor in childhood as the occurrence of malignant tumors at this age is relatively much more frequent than it is in adult life.

Since the report by Mayo and Fauster, nine young girls who had ovarian tumors have undergone operations at the clinic. A study of the clinical history in these cases and a review of the cases reported in the literature revealed certain important facts. While these facts cannot be made to fit every case, yet they are sufficiently common to all the cases to permit one to be suspicious of ovarian tumors when they are encountered.

The first fact that is significant is the history of the pain and its nature. It is usually a mild, dull type of pain which is situated in the right or left lower portion of the abdomen; it persists twenty-four to forty-eight hours and then recurs at short intervals of a week or two. It frequently is related that an enema relieves the pain and this leads to another characteristic, namely, that the pain commonly is not associated with any digestive disturbance. There is no nausea, vomiting or diarrhea. The child may be slightly constipated. When the pain is sharp it is often brought on by active play or by riding in an automobile; it completely disappears in a few minutes to a half hour. The child may then wish to go out and play again.

Sudden attacks of agonizing abdominal pain which are associated with vomiting and much abdominal tenderness do, however, occur infrequently. Wakeley ascribed this to a sudden rising of the cyst out of the pelvis, which causes shock. Twisting of the pedicle, as is well known, may cause the same acute symptoms. In only one of the nine cases in this report was any nausea or vomiting associated with the pain. Girls may have symptomless abdominal tumors.

The physical findings are dependent on the size of the tumor. If the tumor is sufficiently large to enter the abdominal cavity, it is palpable, usually, as a freely movable mass and there is slight associated tenderness. Should the tumor remain in the pelvis and its presence not be suspected, the lesion may be erroneously considered appendicitis. However, rectal examination affords very definite information because if it is made the tumor can be palpated. Because of the small size of the pelvis of a young girl, the pelvis can be very completely explored by bimanual palpation with one finger in the rectum.

As pointed out in the paper by Mayo and Fauster, the acute abdominal symptoms caused by a twisted ovarian cyst may very easily be confused with those caused by an appendiceal abscess. The physical findings of abdominal tenderness and a pelvic mass are likewise confusing. The preoperative diagnosis in one of our nine cases was appendiceal abscess.

Roentgenograms of the abdomen, taken to exclude the possibility of stones in the urinary tract, showed definite soft tissue shadows in the pelvis in three of our cases. In one instance the pres-

†With the Division of Surgery, The Mayo Clinic, Rochester, Minnesota.

‡Fellow in Surgery, The Mayo Foundation, Rochester, Minnesota.

ence of multiple smaller shadows within the soft tissue mass enabled the roentgenologist to surmise correctly that the tumor was a dermoid.

The total leukocyte count and the percentage of neutrophils are of no value in the diagnosis as they may either be elevated or normal.

Report of Cases

Case 1.—A girl, aged twelve years, had had a few mild pains in the right lower abdominal quadrant for six weeks. She had noted that riding in a car would bring them on. The pains had been sharp at times and of short duration; they had lasted about a half hour. There had not been any associated digestive or urinary symptoms. For two days before the patient came to the clinic the pain had been constant and more severe. Examination of the abdomen did not reveal any abnormality but rectal examination disclosed a tender mass in the right side of the pelvis. A diagnosis of appendiceal abscess was made and the abdomen was explored. A hemorrhagic dermoid, which had a twisted pedicle, was found and removed. Convalescence was uneventful.

Case 2.—A girl, aged thirteen years, had darting pain in the right lower abdominal quadrant for four months; the pain had lasted only a few minutes. There had not been any radiation of the pain. The patient had not had any symptoms which were referable to the gastro-intestinal or urinary systems. Examination of the abdomen revealed a large mass which on rectal examination was found to be pelvic in origin. A diagnosis of pelvic tumor, probably a cyst, was made and exploratory laparotomy was performed. The mass was found to consist of a simple ovarian cyst, 5 cm. in diameter, and a hematocolpos caused by a diaphragm-like occlusion just behind the hymen.

Case 3.—A girl, aged thirteen years, came to the clinic because of sharp attacks of pain in the left lower abdominal quadrant; the attacks had lasted about six hours. In the three weeks before the patient came to the clinic, she had had five such attacks; the last one had been accompanied by vomiting. The pain had extended down the anteromedial aspect of the left leg. A tender mass was found in the left lower quadrant of the abdomen, both by abdominal and rectal examination. A roentgenogram of the kidneys, ureters and bladder did not reveal any abnormality and the urine was normal. A diagnosis of twisted ovarian cyst was made. Operation revealed that the left fallopian tube and ovary were twisted on the mesosalpinx with a double twist. A gangrenous fallopian tube and a simple cyst of the ovary, 9 cm. in diameter, were removed.

Case 4.—A girl, aged twelve years, had had a strangulated necrotic right fallopian tube and ovary removed five years before she came to the clinic. In the year before the patient came to the clinic she had had six attacks of pain in the left lower abdominal quadrant; the pain had been relieved by enemas and the passage of gas. On examination, a mass the size

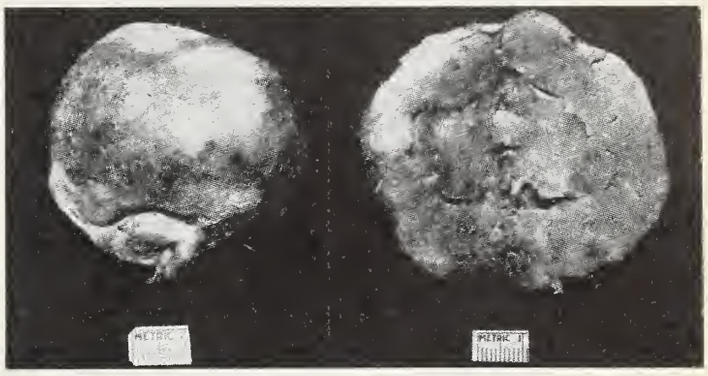

Fig. 1. Gross appearance and cut surface of dermoid cyst removed in Case 8.

of a grapefruit was palpable in the left lower abdominal quadrant; rectal examination confirmed the presence of the mass. A roentgenogram showed a mass of soft tissue in the same region. A roentgenogram of the kidneys, ureters and bladder was normal. A hemorrhagic gangrenous ovary was removed from the left side; it consisted almost entirely of a blood clot.

Case 5.—A girl, aged eleven years, had had frequent attacks of headache, vomiting and abdominal pain for a month before her admission to the clinic. A large abdominal tumor the size of a grapefruit was palpated. A roentgenogram of the abdomen did not reveal any abnormality except a mass of soft tissue. The preoperative diagnosis was ovarian tumor. Exploratory laparotomy revealed a simple hemorrhagic cyst of the left ovary, 14 cm. in diameter; the cyst was removed. The right ovary was 10 cm. in diameter and contained one large cyst and numerous bean-sized cysts. It was removed, but a small strip of ovarian tissue was left. The uterus was congenitally absent; only a stump of the cervix was present. When the patient returned to the clinic four years later she was in good general health and was menstruating from the cervical stump.

Case 6.—A twelve-year-old girl presented herself complaining of left-sided abdominal pain which had begun eight months before she came to the clinic and had continued intermittently. She had had no nausea or vomiting or any intestinal symptoms except slight constipation. Examination revealed a tender pelvio-abdominal mass. A diagnosis of pelvic tumor was made and exploratory laparotomy revealed a hemorrhagic parovarian cyst on the left side and a markedly engorged fallopian tube which had resulted from a twisted pedicle. Both of these were removed.

Case 7.—A girl, aged eight years, had been operated on four months before she came to the clinic. She had had an attack of pain in the right lower quadrant of the abdomen and the right thigh. There had been some abdominal

tenderness and rigidity and a fever of 101° F. Part of a tumor and the appendix had been removed. The same attacks had continued intermittently ever since the operation. The tumor was found to form a mass which completely filled the lower part of the abdomen and was adherent to the small bowel, cecum and sigmoid colon. It originated in the right ovary. The tumor was removed, together with the left ovary, fallopian tube and the uterus, because of their dense attachment. It proved to be a teratoma which contained hair, cartilage, sebaceous material and a multitlocular papillary cystadenocarcinoma, grade 1.

Case 8.—A girl, aged seven years, came to the clinic complaining of dull pain in the lower left side which had lasted one to two days. It had been relieved by an enema and had not been accompanied by nausea or vomiting. These attacks had recurred every one or two months. Three months before the patient came to the clinic, abdominal tenderness, fever and some vomiting had occurred. A diagnosis of streptococcus peritonitis had been made. She was hospitalized for three weeks. Examination showed tenderness in the left lower abdominal quadrant and a large mass which was connected with the uterus. A roentgenogram of the abdomen revealed soft tissue shadows which suggested a dermoid. Accordingly, she was operated on and a dermoid cyst the size of a lemon, which arose from the left ovary, was removed (Fig. 1). It was lying in the cul-de-sac of Douglas and was attached to the uterus and sigmoid colon.

Case 9.—A girl, aged fourteen years, was admitted to the clinic because of sharp pains in the right lower quadrant of the abdomen. The pains had lasted only a few minutes and then had disappeared. These attacks even had awakened her from sleep. She had had no nausea or vomiting. The attacks first had occurred two weeks before her admission to the clinic. Examination revealed tenderness in the right lower abdominal quadrant and some rectal tenderness on the right side. On exploration a tumor the size of a golf ball, which was filled with clotted blood, was found in the right ovary. The tumor and adjacent ovarian tissue were removed; the remainder of the ovary, which appeared normal, was left. The tumor proved to be a corpus luteum cyst.

Comment

The technical problem in the removal of these tumors is usually not difficult. Davidson's suggestion of the use of extreme care in mobilizing a twisted cyst and the placing of a clamp on its pedicle well below the twist before any manipulation is valuable in the prevention of pulmonary embolism following operation.

Summary

We have added eight more cases, which makes a total of sixteen cases in which ovarian tumors have been found among young girls at the clinic. The majority (seven) of these tumors were simple ovarian cysts; four were dermoid cysts; three were carcinomatous cysts; one was a paroovarian cyst, and one was a sarcoma. This seems to emphasize the importance of keeping in mind the possibility of ovarian tumors in young girls, as a fourth of the tumors in this series were malignant.

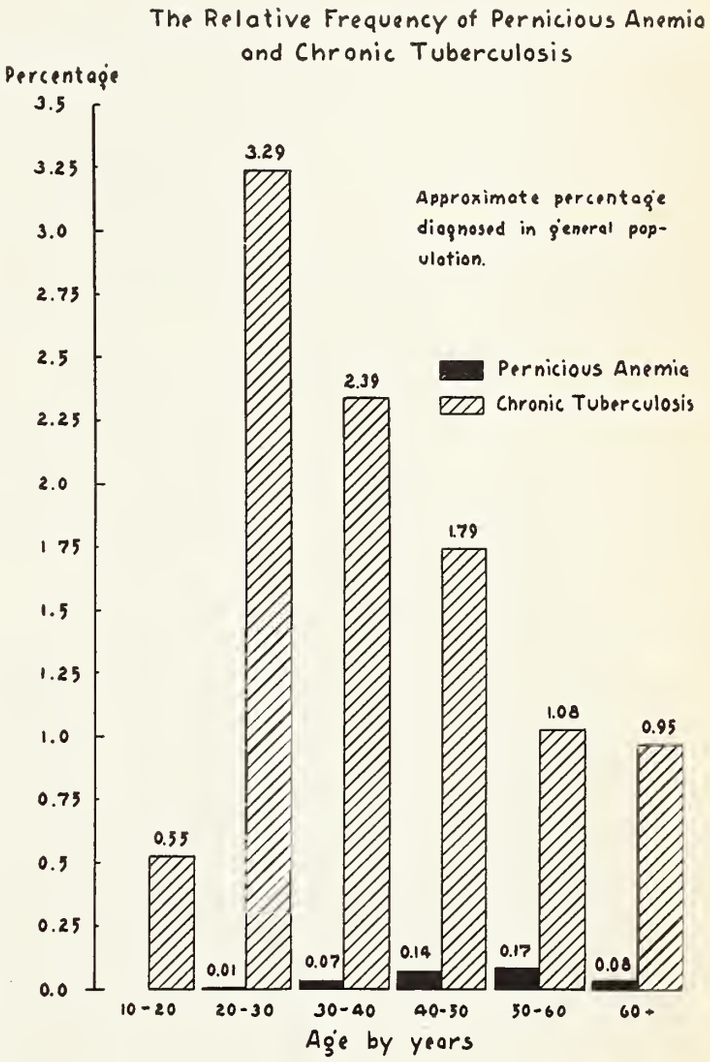
COEXISTING PERNICIOUS ANEMIA AND CHRONIC PULMONARY TUBERCULOSIS*

DAVID V. SHARP, M.D.
Oak Terrace, Minnesota

NUMEROUS theories have been advanced to explain the rarity with which pernicious anemia and chronic pulmonary tuberculosis have been associated. Mathias[4,5] believed that a lack of hydrochloric acid in the stomach produced an unfavorable medium in the tissues for the growth of the tubercle bacilli. This was disproven by Neuberger,[7] who reported a patient with deficient acid secretion as well as coexistent hemolytic jaundice and chronic pulmonary tuberculosis. Neuberger, Meisner,[6] and Leven[3] believed that the toxic substances caused by the tubercle bacilli stimulated the bone marrow in a way comparable with those produced by liver

*From Glen Lake Sanatorium, Oak Terrace, Minnesota, and Minneapolis, Minnesota.

and gastric mucosa. Quarnström,[8] Scheidel,[10] Shandel[11] and Wilkinson[12] explain the rare association of these two diseases in the following way: "Tuberculosis occurs chiefly in young people while pernicious anemia has its incidence in older people, and the association of these two diseases would therefore be rare, and is of no special significance in so far as actual antagonism is concerned."



The material for this study was obtained from the records of Glen Lake Sanatorium and Nopeming Sanatorium, the State Board of Vital Statistics for the year of 1934 and reviews of current medical literature. Since pernicious anemia is not a reportable disease, I have borrowed heavily from the works of Scheidel and of Shandel, who reviewed 269 and 1,127 cases of pernicious anemia respectively. The age incidence tabulated here represents the average of these two similar series (chart).

The age incidence of chronic pulmonary tuberculosis at Glen Lake Sanatorium for the year 1934 begins its rise at the 10-19 year level (5.5 per cent) and climbs rapidly to 32.9 per cent at 20-29 years, from which point it recedes gradually to 9.5 per cent at sixty plus years.

The age incidence of pernicious anemia begins its slow climb at 0-29 years (2.7 per cent) and rises to its maximum point of 33.5 per cent at 50-59 years, from which point it declines to a low point of 6.8 per cent at 70 plus years.[9] The morbidity and mortality rates of pulmonary tuberculosis in Minnesota for the year 1934 are 118 and 30.5 per 100,000 population; a ratio of about 4:1. The incidence and death rate are strikingly similar in pernicious anemia; e.g., 4.9 and 4.4 respectively. Approximately three out of four cases of pulmonary tuberculosis recover. In the event that healing occurs under the age of fifty years, one can well appreciate this factor in the rare co-existence of these two diseases.

Case Report

W. S., a white man, sixty-seven years of age, was admitted to Glen Lake Sanatorium on August 10, 1934, with a history of cough and expectoration of five years' duration, increasing in severity until upon admission he raised two drams of muco-purulent sputum in twenty-four hours. The sputum contained tubercle bacilli which could be seen on stained preparations and which were pathogenic for guinea pigs. For three years, dyspnea had been present to such an extent that it was audibly evident at absolute rest; weakness and weight loss had been present for the same length of time. In November, 1933, he was hospitalized for this complaint, and at that time he had a lemon yellow skin and sclera, pale mucous membrane and atrophic mucosa on the tongue. Numbness and tingling of the

hands was noted. Blood studies, and gastric analysis confirmed the diagnosis of pernicious anemia.

	Nov. 1933	Jan. 1934	Aug. 1934	Admitted Glen Lake
Red Blood Count	1,950,000		3,350,000	
White Blood Count	5,300		5,500	
Hemoglobin	48%	90%	78%	
Morphology	anisocytosis macrocytosis polychromasia neutrophiles shifted to rt. poikilocytosis		anisocytosis macrocytosis polychromasia poikilocytosis shifted to rt. reticulocyte .8%	
Gastric Expression	Free HCl 0 degree		(after Histamine) Free HCl 0 degree	
	Combined 10-15 degrees		Combined 0 degree	
	Total 10-15 degrees		Total 2 degree	

During 1933 and 1934 the patient responded well to liver, iron citrate, and dilute hydrochloric acid, and was discharged in January, 1934, with a hemoglobin of 90 per cent. He reported to the Out-Patient Department of the hospital for liver therapy intramuscularly.

On admission to Glen Lake Sanatorium this patient had far advanced pulmonary tuberculosis of chronic fibroid type as well as cavitation in the left upper lobe. The scleræ were yellow, and the face red; a small easily reducible inguinal hernia was present; the liver

and spleen were not palpable. Vibratory sense was completely absent from ankles to iliac crests and markedly reduced at the wrists; other neurological examinations showed nothing of note. Intensive intramuscular liver therapy was instituted, and the reticulocytes increased temporarily from 0.8 to 2.9 per cent; the hemoglobin from 78 per cent to a level ranging from 85 to 95 per cent (Sahli). The patient thought the numbness and tingling of his fingers had diminished somewhat since admission.

The pulmonary tuberculosis has been practically without change over a fourteen month period of observation. His ultimate prognosis is rather poor and his tuberculosis does not seem to have been aggravated by the associated pernicious anemia.

Discussion

In Shandel's series of 117 cases of pernicious anemia, 69, or 59.6 per cent, are above fifty years of age. Two cases had associated pulmonary tuberculosis to which no special significance was attributed by the author.

From a study of 370 cases of pernicious anemia, Wilkinson feels that many conditions may co-exist with pernicious anemia without apparent causal relationship. Of this series eighty-six (23.3 per cent) had signs or symptoms of other conditions distinct from Addisonian anemia and one (0.27 per cent) showed a co-existence of acute pulmonary tuberculosis. There were no cases of chronic pulmonary tuberculosis.

In an extensive review of the literature, Wilkinson was able to collect only nine cases of chronic pulmonary tuberculosis associated with pernicious anemia before 1933. Of these, four cases were reported between 1903 and 1910 and some doubt may exist as to the diagnosis of pernicious anemia in these patients. Miliary tuberculosis was not mentioned.

In this study of 7,983 admissions to sanatoria for tuberculosis, only one patient was found to have these two conditions. In a series of 16,600 autopsies, Barron[1] found ninety-six cases of pernicious anemia, two accompanied by miliary tuberculosis, and three arrested or healed tuberculosis. He reports two cases of pernicius anemia associated with active pulmonary tuberculosis.

This is the first recognized case of chronic tuberculosis in association with pernicious anemia in 6,600 cases admitted to Glen Lake Sanatorium and 1,383 admissions to Nopeming Sanatorium. There is a marked difference in the incidence of pernicious anemia and chronic pulmonary tuberculosis. This study reveals that the coexistence of these two diseases is extremely rare, and apparently the presence of one has no inhibitory effect on the other.

CENTRAL FRACTURES OF THE NECK OF THE FEMUR TREATED BY INTERNAL FIXATION*

WILLIS C. CAMPBELL, M.D.

Memphis, Tennessee

IN AN analysis of 495 fresh fractures of the neck and trochanter of the femur, the distribution as to location was as follows:

Trochanteric	229
Complete central	214
Impacted central	52

Of those occuring in elderly individuals over seventy, the average age of 108 trochanteric fractures was 78.1; of seventy-eight complete central fractures, 74.6; and of nineteen impacted central fractures, 79.5 years.

Thus, impacted fractures of the neck of the femur and intertrochanteric fractures constitute more than half (56.7 per cent) of these fractures, and in this half, union may be expected in practically 100 per cent, if only approximate anatomic apposition is maintained.

*Abstract of paper read before the Southern Minnesota Medical Association, Winona, Minnesota, August 11, 1937.

Consequently, in any discussion of fractures of the neck of the femur it is most important that differentiation as to location and characteristics be made. Central fractures of the neck of the femur constituted only 43.3 per cent of fractures in and about the neck and trochanter of the femur; only in this group is there any doubt as to securing osseous union. Prior to 1904, it was considered that central or intracapsular fractures did not unite by osseous union.

No one has been a stronger advocate of the Whitman procedure than I, but after seeing the results of Smith-Petersen and others, I have come to the conclusion that internal fixation not only gives a higher percentage of excellent functional results and firm osseous union, but also materially decreases the time in which union is secured, so that weight bearing and walking without support is obtained in from four to six months as compared to six to twelve months by the Whitman method. Also function in the knee and hip is materially conserved, and permanently restricted motion is exceedingly rare. The mortality has been materially decreased by the less extensive means of immobilization and the shorter time of confinement to bed.

My colleagues and I have employed the three-flanged nail in forty-nine cases of complete, central or intracapsular fractures of the neck of the femur. In eleven, the procedure as described by Smith-Petersen was employed, which consisted in a complete exposure of the hip joint and trochanter; in thirty-eight, the nail was inserted through a lateral incision with "blind nailing." The Smith-Petersen technic has been entirely discarded, as so-called "blind nailing" is a less extensive surgical procedure.

The present technic of insertion may be described as follows: Reduction is uniformly accomplished by the well-known Whitman abduction method, so that usually no roentgenogram is made at this time. After reduction, abduction is reduced to about 120 degrees so as to facilitate insertion of the nail. An incision approximately four inches in length is now made over the lateral aspect of the greater trochanter and upper two inches of the shaft exposing the lower half of the greater trochanter and upper two inches of the shaft. A 3 mm. steel wire peg is then placed into an ordinary chuck drill, and the sharp end of the wire inserted into the center of the shaft about three-quarters of an inch below the trochanter. Great care must be taken that the wire drill makes an angle with the shaft of about 45 degrees and is angulated forward about 10 to 15 degrees to conform to the normal anterior deviation of the neck. The wire is now drilled about two inches in this direction, after which roentgenograms are made in both planes which will confirm reduction and the exact direction of the wire drill. If reduction has not been accomplished, a second attempt can be made, but this has not been necessary in any case; also if the wire is not accurately placed, other attempts can be made until the desired direction is obtained. If reduction and direction of the wire are satisfactory, the wire is drilled into the head of the bone to within one-quarter to one-half inch of the joint, depending on the length of the proximal fragment. This is confirmed by the roentgenogram. The protruding portion of the wire is now measured by placing a wire drill of the same length parallel with the protruding portion, and a nail of the exact length selected. I employ a modification of the three-flanged steel Smith-Petersen nail with a tunnel through the center, which is slightly larger than the wire. The nail is then threaded on the wire. A driver with a tunnel in the center is now threaded over the wire and the nail driven through the neck and head by the aid of a heavy mallet. The wire is removed and the driver placed over the trochanter, and the instrument tapped a few times with a mallet so as to closely approximate the fragments. Roentgenograms should not consume more than fifteen minutes, and should be developed and returned to the operating room in five minutes. The entire procedure requires not more than thirty to forty minutes.

After operation, the limb is placed in a Hodgens' splint. At the end of three weeks, roentgenograms are made in order to confirm the position, which we have always found undisturbed. Motion in the knee is instituted at the end of four weeks, when the patient may be removed to his home. At the end of three months, walking is instituted without weight bearing, and at the end of four months, weight is borne on crutches. At the end of five to six months, crutches are discarded if union is firm, as demonstrated by the roentgenogram, which should show trabeculæ transversing the line of fracture. Undoubtedly, it is possible that function may be resumed earlier, but the physiologic status in this location is such that firm union is always slow.

In this series, twenty-one cases have been followed for over one year with 88 per cent solid union; however, nine per cent of these have degenerative changes indicative of a devitalized head with an ultimate prognosis of very poor function. With improvement in technic and further experience, 80 to 85 per cent solid osseous union with a good functional result can be anticipated.

CASE REPORT

POISONING WITH CICUTA MACULATA OR WATER HEMLOCK

CLYDE A. UNDINE, M.D.

Minneapolis, Minnesota

CICUTA is a highly toxic plant. Many deaths amongst men and animals have been traced to this plant. This plant is also known as Wild Parsnips, Water Hemlock, Cowbane, Beaver or Muskrat poisoning, Children's Death, et cetera. This is one of our most common swampweeds, growing abundantly along streams, ponds, ditches and wet meadows, throughout the Eastern and Central portions of the United States.

Since the middle of the sixteenth century, Cicuta has been recognized definitely in the United States. It has sometimes been confused with Conium which was a poisonous hemlock given to Grecian and Roman criminals. The poison was probably Conium or extracts and mixtures of several other poisonous plants. It was this plant which was probably similar to Cicuta. The symptoms of Socrates' death which were recorded in detail bore no resemblance to those of Cicuta poisoning.

Conium was studied in 1541 very accurately by Konrad Gesner. He gave the name Cicuta Aquatica to Water Hemlock.

Cicuta Maculata is a perennial and a member of the parsnip family. The Cicuta plant has a hollow green, jointed stem which grows from three to six feet high, and has narrow leaves divided several times. It has a small green-white flower with dense clusters. The root has a bunch of spindle shaped shoots which give forth a yellow, gummy secretion similar to that of the parsnip. This secretion is sweetish, and not disagreeable to the taste, so that adults and children have eaten quantities sufficient to prove fatal.

From other umbelliferous plants, the roots are differentiated by the presence of numerous transverse chambers which are seen in a section. Cicuta differs also from garden parsnips with which it is sometimes confused in that the parsnip has yellow flowers, one single root, a leaflet which has a broader stem and which is rough, and the plant is not necessarily grown in wet places.

In 1679 Wepfer recorded the symptoms of Cicuta poisoning, giving a detailed account of five children who were fatally poisoned. He dwelt particularly on the non-coagulation of the blood. Later in 1723 Weimann described the poisoning of two students. In 1756 Schwenke recorded the poisoning of four children in the village of Overschie. A New Englander, Stockbridge, in 1814, gave the first public account in this country of Cicuta poisoning. He described the poisoning of three patients, one dying in violent convulsions. M. R. Stratton published an account of the poisoning of eleven boys in Denver, two proving fatal. This is the greatest number of cases of Cicuta poisoning reported by any one observer up to the present time. In a review of the literature of this subject, Egdahl included a total of 47 cases, but it doesn't seem possible that this represents the entire number of poisonings due to Cicuta.

Toxicology

The poisonous resin of this plant was first isolated in 1876 by Bachm who named it cicutoxin. An aromatic, yellowish, oil like-substance exudes when the root stock is cut and the odor is similar to parsnip. The toxin has been described as a clear plant resin, which is sticky and soluble in either chloroform or alcohol. The leaves and stems are less toxic than the root stocks. This plant is most poisonous during the spring. During the growing season, the stored material is absorbed in the development of the plant and is of course then less virulent.

Necropsy examinations have reported the following findings:

1. Emphysema and edema of the lungs.
2. Non-coagulation of the blood after twenty-four hours.
3. Multiple hemorrhages.
4. Generalized congestion of the central nervous system.
5. Widely dilated pupils.
6. Glomerular nephritis.

Report of Cases

On June 14, 1924, I was called to attend two boys nine and thirteen years of age who had been taken suddenly ill. They had been dismissed from their classes at 3:30 P. M. apparently well, and immediately went to play. At 5:15 the boys were eating their evening meal. The parents observed that they appeared pale and sickly and that they refused their supper. One of the boys asked permission to leave the room, complaining of nausea, but before going very far, fell to the floor with violent convulsions. When I arrived, twenty minutes later, the older child was in a convulsion and the other was vomiting and appeared seriously ill. The children were evidently suffering from some sort of poison. I soon found out they had eaten of a plant, the nature of which was unknown to me at the time. There was a plat of swamp land adjoining their home in which water hemlock grew

SURVEY OF PIONEER MEMBERS OF THE ST. LOUIS COUNTY MEDICAL SOCIETY

By RICHARD BARDON, M.D.

IN TWO previous chapters an attempt has been made to trace the development of the medical profession in Duluth and St. Louis County, and to record the contribution of the men who practiced during that period. These men are well known to the older members of the society; some are still living and in active practice. It is not possible, in this narrative, to include detailed biographies of all the pioneer practitioners. The selection has been made somewhat arbitrarily on the basis of available data. The choice casts no reflection on the records of those who are mentioned by a few lines or paragraphs only. They were all pioneers in the civic and medical development of the county, and many will go down as "unsung heroes," who played their part in serving the community.

It is not the scope of this chapter to mention in detail the records of the surviving members of this early group, although it is difficult to pass by some names without giving them a salute. Such recognition is fitting not only because of their seniority in membership but because of their unselfish labors in the field of medicine, and the honors they have brought to the profession.

The appended list includes the names of the practitioners from 1883 to 1900, as appearing in the city directories. Doubtless, this list is incomplete, and it is to be hoped that the material presented in this brief series of papers will serve as a framework for future definitive research.

Acknowledgment is made to many who contributed data or suggestions used in this compilation: Dr. J. M. Armstrong of St. Paul, Dr. E. L. Tuohy, Dr. D. L. Tilderquist, Dr. C. A. Scherer, Dr. S. H. Boyer, Sr., Dr. W. A. Coventry, Dr. C. F. McComb, and Dr. A. E. Walker of Duluth.

William H. Magie

Duluth had a population of about 10,000 when Dr. Magie arrived there in 1884. William Henry Magie was born at Madison, New Jersey, September 30, 1854. When he was three years of age his parents moved to Henderson County, Illinois, and from the time he was about seven until he was fifteen he lived with the family in Chicago. Dr. Magie acquired his early education in the public schools in Chicago and Abingdon College at Abingdon, Illinois. In 1874, the family moved to Kansas, then recently freed from Indian occupation. The family settled on a ranch, and the father became an extensive rancher and a man of prominence in Kansas affairs during the seventies and eighties, being elected to the state legislature. Dr. Magie lived on the Kansas farm and ranch for several years, and previous to his medical training spent a year in a drugstore at Pittsburg, Kansas, and in 1882 entered the College of Physicians and Surgeons at St. Louis. He was graduated in 1884, and after a brief practice at Pittsburg, Kansas, arrived in Duluth, September 10, 1884. During the first fifteen years of his life in Duluth, he devoted himself to the arduous work of the general practitioner, but subsequently confined his work to surgery. Dr. Magie was for twenty-eight years of-

ficial surgeon of St. Mary's Hospital. He was president of the Minnesota State Medical Association in 1908. He was also a Fellow of the American College of Surgeons, and a Fellow of the Western Surgical Association.

Dr. Magie died in 1932. The following tribute, written by Dr. E. L. Tuohy, is of unusual interest:

Tribute by Dr. Tuohy

The safe exhibition of ether anesthesia in anybody's hands; high pressure sterilization, with proper ligatures and instruments for hemostasis; hospital beds and twenty-four-hour nursing—these and many other developments skyrocketed surgery into unexampled prominence after 1880. However, none of these developments could have come without the direction and intuitive judgment of men who, though not to be classed either as pioneers or researchers, became the great operating surgeons of that epoch. They were not the McDowells, the Rushes, the Beaumonts, or even McBurneys. They developed independently here and there, usually in association with a hospital backed either by a nationalistic group or a religious order. Thus did Dr. J. B. Deaver advance with the German hospital in Philadelphia, J. B. Murphy with Mercy Hospital in Chicago, W. W. Mayo and his celebrated sons with St. Mary's in Rochester.

In like manner, but obviously in a lesser orbit, did William H. Magie advance himself to prestige and position in connection with St. Mary's Hospital in Duluth. The very distinguished daughters in the St. Paul family of Kerst (Mother Scholastica and Sister Alexia) put their lives and their considerable fortune at the disposal of the Benedictine Order in Duluth. Their present hospital was opened in 1898. Few investments of soul and money have ever produced better dividends. To Dr. Magie goes the honor of having been the surgical standard bearer who did for Duluth and vicinity what others were doing in something of the same tempo throughout our Middle West.

He left his impress in countless ways. He was honored by the profession at home and respected abroad. He was one of the earliest industrial surgeons, and under him many young men secured a first-hand introduction to the realities of practice that made them very successful men. His manner was not ingratiating. He was given to rather grandiloquent criticism of his fellows, and particularly his later competitors. This led no one to fail to appreciate his great diagnostic powers and technical competence. At a time when few laboratory and no x-ray aids were available, fancy what men of his type and essential isolation were pitted against. Malpractice suits threatened even as now, and without office or hospital records of any consequence such men relied upon their judgment and memory to a degree few of us may appreciate.

Dr. Magie performed the first appendectomy in this region at the old St. Mary's Hospital (now St. Ann's Home for the Aged) in the year 1891. He performed the first gastro-enterostomy done here in 1895. For some years, I recall his use of the McGraw ligature type of anastomosis. He was a tireless visitor to medical sessions and surgical amphitheatres here and there. He was prone to retail the exploits of men like Ochsner, Deaver, Charles A. Wheaton of St. Paul, and Bernays of St. Louis (one of his early teachers). He handled fractures as cleverly as he supervised typhoids. With a twinkling eye he enjoyed nothing better than to regale the operating room troupe with gossipy comments of the day. For example, "I saw a new sign on our building today. A recent addition to our profession announces that he is to treat 'Diseases of Women and Children.' That's a fine idea. For years I've specialized in 'diseases of men, women and children.'"

Behind all the banter, however, was a devoutly keen appreciation of the duties and privileges of those who find themselves the masters in our guild. It was his way to discipline and teach, and be it said to his very great credit—he played no favorites.

When the Steel Corporation built the new plant at Gary, on the St. Louis River, a fine unit hospital was built, and to it he transferred his work. In addition, he was medical consultant for several railroads and industrial plants. As his health failed, however, he returned to St. Mary's Hospital, where, after a lingering illness, he died. His early devotion to the interests of the Benedictine Sisters when his faculties were at their zenith brought him peace and surcease, as well as loving care, in his long, racking, final illness, with the tragic discomforts of myocardial weakness from coronary decay.

It may be said, without disparaging the work of any other men, that Dr. Magie, above all others, set the goal of honest and square dealing for this area as between doctor and patient; and he who was critical to a degree, at times, of others was equally severe with himself where he felt judgment had failed him. He was generous to a fault, and had the feeling of many who went through the panic of ninety-three that it was absurd to store up any savings. This thought may well obtrude at a time when history in the repetition may well be in enactment.

Apropos of Dr. Bardon's comments upon styles in horses and buggies for St. Louis County doctors, Dr. Magie had a spanking pair of bays, that vied for preeminence with the very exceptional equipages that were the pride of the Head of the Lakes at that time. The musk-ozen robes and beplumed cutter-like droshky are well recalled. He joined with many men of prominence in establishing hunting and fishing lodges on Isle Royale and elsewhere. The old guard in the State Medical Association knew him well. They elected him president at a Duluth meeting in 1908.

John J. Eklund

By E. L. Tuohy, M.D.

Dr. John J. Eklund practiced in Duluth from 1885 to the time of his death in 1922. Born in Hälsingland, Sweden, March 13, 1861, he came with his parents and family to Taylors Falls, Minnesota, at the age of five. He became ultimately the leading Scandinavian surgeon at the Head of the Lakes.

It is both impossible and improper to attempt to evaluate his useful career apart from the great migration to Minnesota of Swedes, Norwegians and Danes, which began shortly after our war between the States. The virile, individualistic and intelligent immigrants truly made great portions of Minnesota a new Viking stronghold. They came with their ministers, teachers, doctors, and other qualified artisans. Dr. Eklund typified the best among them to such a degree that these items may well become a part of a discussion of his life. These men and women held very closely to their home traditions and religion. It is conspicuous, for example, how many of our present-day Minnesota physicians are sons of Scandinavian ministers. While Dr. Eklund was not a minister's son, he early fell under the influence of the Church in his formative adolescence, and lived with an uncle, Reverend Engdahl, at Cambridge, Minnesota. He never forsook nor forgot this native religious guidance. It was one of his attributes, coupled with his sturdy body and honest mind, which led him directly into the confidence and esteem of thousands of his like-thinking compatriots.

He continued his education, still under Swedish guidance, at Gustavus Adol-

phus College in St. Peter, Minnesota. For a number of years after 1893 he was a director of the College. It would appear that it was in St. Peter that he met Miss Nannie Asp, whom he later married in Duluth in 1888.

He received his medical training at the old Minnesota Hospital College, which later became the Medical Department of the University of Minnesota. Thus, it appears that he came under the tutelage of doctors who not only introduced him to American Medicine but American life as well. This was likely important, for Scandinavian doctors, trained before coming to America, often found great difficulty in adjusting their attitudes to the obvious novelties inherent in the development of the new land. Dr. Eklund suffered none of the restrictions upon manner, personality, approach or conduct imposed by a transfer so late in life. His was the great combination of deep traditional, religious and intellectual certainty gleaned from his clear-thinking Swedish forebears, upon which was engrafted an outlook and political urge, the product of living in a fertile and at that time unfettered land.

It is easy to see, therefore, in retrospect, how he developed along so many lines. A worthily religious man, he liberally supported his own church, not condemning other denominations; he acquired a high degree of surgical judgment and technic without in any way disparging the work of others; he became almost a political seer and prophet, without ever asking for himself any conspicuous position; his business judgment led him to relative financial affluence, untrammeled by the envy of anyone, or leaving the evidence of wreckage, so often the obvious result of competitive ruthlessness.

It is true that he was elected Coroner for St. Louis County in 1898; he served on the first charter commission of Duluth, and was chairman of the Board of Health Committee of the Duluth Water and Light Board. Later, he was Presidential Elector at large for Minnesota in 1908. However, these and many other responsible and honorary positions he took in his stride. They did not keep him from successive visits for graduate courses and instruction in New York, Baltimore, Chicago, and elsewhere. In later years, he was associated in the management of two important Duluth banks, but maintained the keenest interest in all medical activities, and assisted greatly in the development of the Duluth hospitals.

Few men were ever more beloved among the profession for what they actually were. The writer best recalls certain personal attributes that memory retains of the period of about 1905: He had a very black Vandyke beard, always well trimmed. At the same time, he had a very heavy, black horse. This horse had acquired the faculty of lying down gracefully while harnessed and within the traces and tethered to a hitching post, the while he awaited the convenience of his master. After long days of calls and hospital duties the doctor's meals were likely rarely on time. Then, as was the custom, he had interminable evening office hours. Just across from his office was a theater which ran two evening shows. On occasion, the genial Dr. Charles F. McComb and his wife were planning to attend the second show. "Isn't it fine," remarked Mrs. McComb, "see, the crowd is just leaving the first show: the street is full of people." "You are wrong, my dear," Charles F. replied, "that is not the theatre crowd—Eklund is just closing up his office!" In those same offices, where he saw so much of life and granted its furtherance to many, came also his death. A demented man took his life and his own under some awful twist of the human consciousness which no one may ever understand.

Mrs. Eklund died in 1905. Their son, Dr. William J. Eklund, born in 1890, is now a member of the Minnesota House of Representatives, and president of the Duluth National Bank, which his father helped to organize.

Charles Adams Stewart

In 1887, Dr. Charles Adams Stewart arrived in Duluth. Dr. Stewart was born in Sandusky, Ohio, on June 23, 1848. He was educated in the public schools of Sandusky, took a course at the Western Reserve Normal School, and graduated from the Medical Department of the University of Iowa, at Keokuk, in 1870, with a degree of M.D. He then returned to Ohio and practiced a while before entering the Medical Department of Western Reserve University, from which he was graduated in 1877. He then practiced in Marinette, Wisconsin, for about six years, later moved to Chicago, where he was in practice for about four years; and finally located in Duluth.

Dr. Stewart was one of the pioneer surgeons of the city, and the following description, written by Dr. E. L. Tuohy, who knew him well, is most interesting:

Dr. Stewart—The Man

By E. L. Tuohy, M.D.

As will be seen by this recital of his activities, medical and otherwise, he came to Duluth with "great expectations." Eighty-seven was not long before Ninety-three—the depression period that all those who passed away before 1929 looked back to as a chapter of despair that would never be repeated. Charles A. Stewart was one who stood in line for hours at the old Land Office in Duluth ready, when the minute and hour arrived, to make certain "filings" on the property near the upper St. Louis basin near Spirit Lake. With visions of an amplified Chicago in Minnesota, this land near the future docks had exceeding potential value, at least in the minds of those who at the same time swarmed into East Superior and laid out a city that fifty years later was said to have "usurped a lot of fairly good farm land." In any case, Dr. Stewart later said, when he sold his acreage to the Steel Company for part of its present site, "I received for it almost exactly what I paid for it, and had the honor of paying taxes on it yearly in the quarter-century interim."

Nevertheless, while his speculative ventures wound up in the conventional way, the failure to amass a fortune likely saved him for an extraordinarily useful and successful medical life. Among those who practiced in Duluth at the turn of the century none more decisively exemplified the doctor of poise, alertness, polish and resourcefulness. Endowed with indomitable will and self control, he held a rigid rein on his patients. So long as they obeyed him faultlessly he was their abject slave, calling on them at any and all hours, with total disregard for his own convenience and comfort. If they questioned his judgment or ventured to seek counsel elsewhere he maintained his equanimity if he could, and if he couldn't his sarcasm and irony were as superb as any of Voltaire's. Said a fluttery grand dame to him on occasion: "But Doctor, I am only going to get their opinion." "Yes," he replied, as he characteristically nodded his head and drew up the corners of his mouth sardonically, "and when you return you will have their opinion in a bottle."

He practiced in some four medical decades when it was all right to specialize in the eye or maybe at times the ear . . . but for the most part, every he-man doctor should be equal to the care of anything at any time. The growth of specialism in later years distressed him, as it did many others who saw the "family" stepping out and choosing their own type of doctor, even as they did their political party or religion. Some of us, today, could have learned much from him, and not a few did. He believed in therapeutics, and had a polished sequence of vehicles and adjuvants that were only exceeded by his extraordinary finesse in getting about among his patients. On occasion he told the writer, "You must enter a

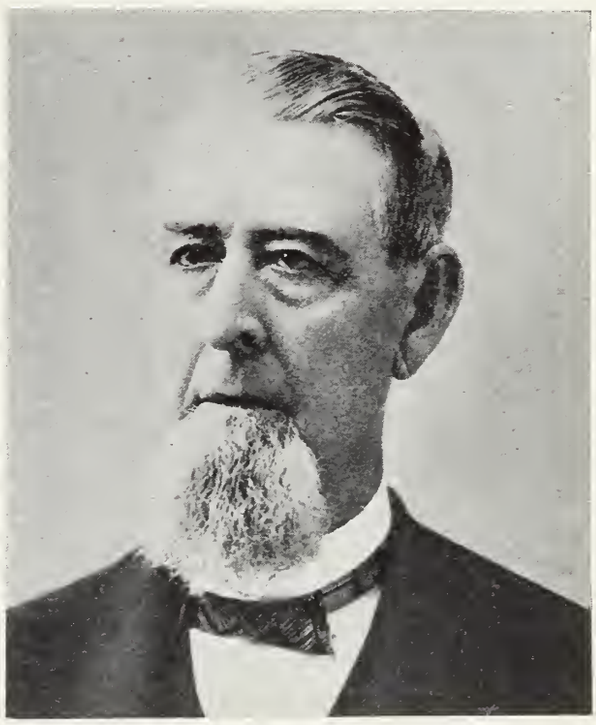
house; examine the patient, doing all that is essential for his comfort and outlook; speak to the family and give full reassurance; gain access to the hall and hat rack; leave as if in no hurry whatsoever, and be in your buggy and on your way in five minutes." Please remember, those were the days when "contagion" and "typhoid" bulked large in practice; when hospitals housed emergencies and transients; and when the doctor was supposed to be able to forecast the exact hour when crises, like comets, were to appear. A consultation was no casual affair, and to a young man it was a brilliant lesson in dignity. It was particularly awe inspiring when men like Drs. Stewart and Magie appeared in consultation and showed each other that courtesy of approach and expression that was most exalting; but when they foregathered singly and candidly gave their real opinions it was indeed a sorry reflection of how discordant personal competitive attitudes could so widely separate such truly gifted men.

They lived through the beginning of a period when our territory turned from lumbering to mining. Saddle-bag medicine had gone, but the "Horse and Buggy Age" was producing a coterie of independent folk in all lines who, at least, had their "feet on the ground" a goodly portion of the time. The highways and cars had not as yet despoiled the hamlets and assembled the urban pack of people who seem to serve mass service as well in Medicine as in Politics. So, when Dr. Stewart suffered a hemiplegia, sudden and permanent, he was in no mood to quit. To the writer he actually said, "Cut the damn leg off and I'll get down and sit in my office all day." He knew that if he had been able to get there a lot of old patients who worshipped him would come to see him.

A man wonderfully read, his mind was stored richly with wisdom, and he had the great gift to illustrate it with anecdote and reminiscence. It is not likely that he left any published papers, but he read many before local and state societies. Fate dealt kindly with Medicine, as it often does, when his trip to the Head of the Lakes, in search of fortune, ended his finding instead fame and friends.

A. J. Braden

The following résumé of Dr. A. J. Braden's activities was taken from the records of the Society:



Dr. Braden was born in New London, Ontario. He sprang from the sturdy Revolutionary stock of the state of Maine. While still a boy, his parents migrated across the line to the small town of Climax, Michigan, and here the Doctor received his grade school education, high school at Battle Creek College, and his college education at the University of Michigan. At the age of twenty, from 1880 to 1884, he served in the United States Army, most of the service on the Texas border. The urge for further training took him back to the University of Michigan, where he graduated from the Medical School in 1888. He must have loved this North Country for he went directly from his medical course to the shore of Lake Superior and practiced his profession at Munising from the time of his graduation until he changed location to come to Duluth in 1893. The work in upper Michigan must have been strenuous. He frequently related tales of the hardships of the practitioner in the earlier days of the upper Peninsula.

While in Duluth, he carried on as a general practitioner, acquiring a reputation as a keen diagnostician and a careful surgeon. Several postgraduate courses in surgery led him to closely limit himself in this field. In recognition of his work, he was admitted to fellowship in the American College of Surgeons among the earliest of the Duluth members. During his later years of practice he did much orthopedic and industrial surgery. He introduced various younger men to the practice in Duluth and several of our outstanding physicians thank Dr. Braden

for the training received from him. The doctor was very assiduous in attending all local medical meetings, and was always prepared to discuss scientific papers. While never pushing himself he was always active in medical and civic affairs and held many offices. During the late war he served on the draft examining board. He was also the examining physician for the Shrine Hospital for Crippled Children for Duluth from its foundation.

Other Early Practitioners

Among the many early practitioners, A. F. Ritchie may be mentioned. He was a graduate of McGill in 1876, a charter member of the Society; a man of wide training, and of unusual skill in his profession.

Dr. Vespasian Smith

Dr. Smith figured frequently in the early civic and medical development of Duluth. An account of his life may be found in the preceding chapter on "Organization of the St. Louis County Medical Society."

Frank O. Sherwin, also a charter member, a graduate of Rush in 1878, was Health Officer for many years.

George W. Davis, a graduate of the University of Detroit in 1879—a pioneer physician and obstetrician—built up a large practice. He died May 4, 1923.

Jonas M. O. Tufty, a Norwegian by birth and medical training, was probably the first of his nationality to practice in St. Louis County.

Frank N. Phelan received his training in Wooster, Ohio, in 1884, and achieved a large following.

Horace Davis was graduated from Dartmouth in 1884; arrived in Duluth in 1888.

A. C. Taylor arrived in Duluth in 1889. Dr. Taylor was born in Michigan, May 4, 1848. He graduated from the University of Michigan in 1874, and practiced in Manchester, Michigan, for fourteen years, coming to Duluth in 1889. Dr. Taylor was actively identified with the organization and operation of the Training School for Nurses at St. Mary's Hospital. Although he engaged in general practice, he was particularly interested in Surgery, and at one time was local and consulting surgeon for the Duluth and Iron Range Railroad. He died suddenly on April 21, 1926.

J. A. McCuen was born January 27, 1864, at Guelph, Ontario. He was graduated from Toronto University in 1891, arrived in Duluth the same year, later serving as Mayor of the City in 1912-1913. He died in November, 1927.

Pioneers Still in Active Practice

There are some twelve men whose arrival in Duluth places them in the pioneer period, although most of them are still in active practice. Among these are Dr. F. C. Bowman, born March 26, 1849; graduated from Hahnemann, Philadelphia, in 1881; located in Duluth the same year. Dr. D. C. Rood arrived in Duluth in 1888. A detailed sketch of his life is included in a paper by Dr. O. W. Parker, "Pioneer Physician of the Vermillion and Missabe Ranges of Minnesota," to be published subsequently. Dr. A. E. Walker, a graduate of Bellevue Hospital Medical College in 1890, has practiced continuously in Duluth since June, 1890. Dr. Mary McCoy, Michigan 1890, arrived in Duluth, July 8, 1890. Dr. Homer Collins practiced first in Rochester, Minnesota, for five years; then located here in September, 1890. He was graduated from Physicians and Surgeons, New York, in 1884. Dr. S. H. Boyer, Sr., arrived in Duluth on New Year's Day, 1891, and opened his office January 20, 1891, in the Norris-McDougall Block at No. 7 West Superior Street. In 1896, he was elected president of the County Medical Society, with the following slate: "President, Dr. S. H. Boyer; Vice President, Dr. Mary McCoy; Second Vice President, Dr. A. J. Braden; Treasurer, Dr. S. C. McCormick; and Secretary, Dr. C. R. Keyes." In 1930, Dr. Boyer was elected president of the State Society. He is in active practice, and has aided materially in the preparation of this paper.

Dr. C. R. Keyes graduated from Vermont in 1881; located in Duluth in 1891, after practicing in Olmsted County for nine years. Dr. Robert Graham graduated from Detroit Medical College in 1893, and has practiced in Duluth ever since. Dr. Peter Kraft took his medical work in Munich, 1892, coming to Duluth in 1893. Dr. J. M. Robinson, a graduate of Pennsylvania in 1891, came to Duluth in 1893; was a general practitioner, later specializing in Eye, Ear, Nose and Throat. Dr. William R. Bagley is a graduate of Michigan, and has practiced in Duluth since June 30, 1898; he is a past president of the County Society.

Charles Frederick McComb has been in continuous practice in Duluth since 1883. He was born at Stillwater, Minnesota, August 7, 1857, the son of James G. and Eliza Jane McComb. His father, a native of Pennsylvania, lived in Iowa, and subsequently became a territorial pioneer in Minnesota, and for many years was in business at Stillwater. Dr. McComb grew up in Stillwater, and spent two years at the State University, and after beginning his studies under Dr. P. H. Millard at Stillwater, entered Rush Medical College in Chicago in 1877, graduating in 1879. For three and one-half years he practiced in Rush City, Minnesota; then, following a postgraduate course in New York City, he located in Duluth.

Dr. McComb has twice been president of the St. Louis County Medical Society. He was the first president of the Interurban Academy of Medicine, and was president of the State Medical Society in 1887, being the first physician of Duluth to be so recognized. He was also a member of the State Board of Health under three governors. He served as Coroner of St. Louis County for two terms in the eighties, and in 1912 was appointed County Coroner, and has held that office continuously by election. During the World War, Dr. McComb was a medical officer on board the battleship Iowa, and was discharged from the Navy with the rank of Lieutenant Commander. Dr. McComb is the only living charter member of the St. Louis County Medical Society, and it is peculiarly fitting that an account of his life should bring to a close this "Survey of Pioneer Physicians of Duluth and St. Louis County."

Cancer Control Campaign

CANCER today is one of the outstanding problems of medicine and public health. Because of its rapid advance as a cause of death in the past few years, cancer has aroused considerable interest. It is fortunate that the American Society for the Control of Cancer has, as its managing director at this time, such an able leader as Dr. Clarence C. Little of Bar Harbor, Maine. Dr. Little, a former president of the University of Michigan, who was recently appointed to the National Advisory Board on Cancer by Mr. Morgenthau, did much to stimulate and assist the State Committee and those interested in the local control of cancer by his recent visit to the Twin Cities.

While here, he addressed professional groups and a large lay audience. He emphasized that cancer is an individual problem and that the control of cancer lies with the cancer patient and his physician. *What* is done and *when* it is done largely determines the outcome of every case. He called attention to the fact that there are no community aspects to the cancer problem. Improvement of housing, protection of foods, purification of milk, water, and sewage, have no effect on cancer incidence.

The unwillingness of the layman to hear about cancer is being rapidly broken down. Daily it is becoming easier to enlist the interest and cooperation of laymen in the educational program. This fact makes it important to control and direct this lay interest into proper channels. This is the job of the medical profession, individually as well as a group.

While the fundamental research into the cancer problem is now focused more on the fields of chemistry, physics and biology, than on clinical fields, it remains for the clinician to apply these findings to the saving of lives and to the prevention of the disease. This means that he must keep abreast of the knowledge in these related fields.

The cancer death rate in Minnesota is much higher than for the country as a whole. Today, approximately every eighth death in the state is due to some form of malignant disease.

By coöperating fully in the cancer educational campaign being sponsored by the Women's Field Army of the American Society for the Control of Cancer, especially the campaign for periodic examination to detect the beginning of cancer, the medical profession can create an influential body of opinion favorable to the ideals for which the profession stands, thus strengthening its stand against the encroachment of destructive forces. It is believed that from one-third to one-half of the 150,000 annual cancer deaths in the United States could be prevented if existing knowledge about the control of cancer would be utilized by the medical profession and the

public. It is known that cancer in some sites, such as the skin, mouth, breast, and uterus, offers from 75 to 95 per cent chance of a five-year cure if treated before metastasis occurs.

That early cancer is curable is shown from the latest report of the American College of Surgeons, which has reported more than 29,000 five-year or longer cures of authenticated cases.

M. N.

Pulmonary Embolism

NOT much progress has been made in the control of pulmonary embolism since the true nature of embolisms in general was first disclosed by Virchow in the middle of the last century. Three types are readily apparent: those in which death occurs immediately, those in which death is delayed for a few hours at most and those which recover spontaneously. Obviously, for those in the first class, nothing curative can be done, for they are dead before a finger can be raised. Preventive measures have accomplished very little. Various drugs which delay the coagulation time of the blood have been used, without definite benefit. Increasing the patient's bodily activity while convalescing in bed from surgical operations, parturition, accidental injuries, et cetera, in the hope of stimulating the peripheral circulation and preventing the stagnation and thrombosis in the lower extremities, which so often is found to be the basis of these emboli, has come into general use and is undoubtedly useful, but as yet the incidence of pulmonary embolism has not shown any material reduction. Patients continue to die sudden, tragic deaths just as they are about to leave the hospital, or have reached a point in their convalescence when everyone concerned is looking forward to their complete recovery in a short time. It is the most catastrophic calamity in all professional experience and few practitioners escape meeting it, sooner or later. In the present state of our knowledge we are very helpless when it happens.

In the third class, where recovery occurs spontaneously, it is questionable whether treatment of any kind makes much difference. Sedatives and vasodilators are generally used, likewise oxygen inhalation, and when the patient recovers these agents receive the credit, but it is difficult to believe that such medication can have any direct influence on a mechanical situation like this, where at least one fairly large embolus, or a "shower" of smaller ones, is plugging branches of the pulmonary artery.

It is in the second, or intermediate, class that the most definite advance has been made in curative treatment and where the greatest opportunity for further improvement is being anticipated. It was for this type, where the patient survives the onset of profoundly serious symptoms long enough for something to be done, that Trendelenburg devised his operation of pulmonary embolectomy, in 1907. Although he and his assistants tried it a number of times the attempts were always unsuccessful and it was not until the year of Trendelenburg's death, in 1924, that Kirschner had the first case of recovery. In all, there have been nine fully successful operations, all performed by Swedish or German surgeons. This would lend more encouragement, if there were not so many barriers to be surmounted. One of the greatest of these is the possibility of spontaneous recovery without operation and this has led Nystrom, who has had two successes, to postulate that only the obviously dying should be subjected to the operative treatment. Other obstacles are readily seen, especially in this country, where the surroundings and the medico-legal aspects are not nearly so well adapted to quick and effective action in these highly emergent situations as they are in the older countries.

The recent work of Leriche and his associates in the infiltration of the stellate ganglion with procaine solution invites serious attention. It is based on the hypothesis that the vasomotor reflexes play an important part in the mechanism of death in pulmonary embolism. At least the suggestion contains the merit of a simple technic and an absence of operative risk, but whether it will accomplish anything remains to be seen, for the experience of its progenitors is far too scanty, as yet, to warrant forming any definite conclusions.

G. C.

Nazi Persecution in Vienna

THE tragic events which followed the "anschluss" of Austria last month have involved not only political figures in Austria but prominent members of the medical profession in Vienna. That so many physicians, most of them

Jews, should have preferred death to certain persecution under Nazi rule is an indication of what has been taking place in Germany.

Among those who have already committed suicide are Professors Wolfgang Dent, Gabor Nobl, Edmund Nobel, Arnold Baumgarten, Moritz Oppenheim and Jonas Borak of Vienna and Gustav Bayer of Innsbruch. Professor Sigmund Freud, of international fame, despite his eighty years and recent illness, is reported to have been robbed and prevented from leaving Austria. The fate of Professor Heinrich Neumann, the outstanding ear and throat specialist of Europe, hangs in the balance. It was he who got "in Dutch" two years ago by his refusal to operate on Hitler for a supposed cancer of the throat, on the ground that his nationality would be blamed in case of an unsuccessful outcome.

Hitler's usurpation of power which is an outstanding political phenomenon of all ages was made possible and in the eyes of many was essential because of the lawlessness and political chaos in Germany following the war. The same train of events came to pass in Italy and the situation in Russia is different only in that the dictator calls himself a communist instead of its foe. One man is the law maker, judge and executive and to maintain his position must also be the executioner.

While we do not for a moment believe that all Germans approve of the ruthlessness of Nazi methods, those who voluntarily support the Nazi régime give their approval to the present German political philosophy which has shown itself paganistic in its attitude to Christianity, not only unchristian but barbarous in its treatment of political opponents and Jews and has for the time being at least suppressed all ideas of individual rights and freedom for which democratic countries have fought for centuries.

"The Birth of a Baby"

THE American Committee on Maternal Welfare has prepared an educational film entitled "The Birth of a Baby" which is now being shown in regular moving picture theaters with an admission charge. Health leaders have used the printed page, radio, exhibits, and to some extent moving pictures as educational media. The chief drawback of most of these methods has been the limitation of audiences to individuals of certain types. A public moving picture with sufficient dramatic interest should be an ideal method of reaching all types of people. "The Birth of a Baby" shows this to be true.

The functions of health education are to allay fear through understanding of the body, to emphasize the importance of preventive measures, and to stress the value of early diagnosis and treatment. Since the chief interest of most people is their health, the demand for such information is very great. To be effective it must originate from reliable medical sources. The moving picture entitled "The Birth of a Baby" was supervised in its making by five eminent obstetricians connected with leading universities and hospitals. The committee's effort has the endorsement of such organizations as the American Medical Association, United States Public Health Service, American College of Surgeons, and American Public Health Association.

For some time motion picture producers have known of the public interest in medical subjects. Hampered by tradition in producing other types of pictures, medical films with a few exceptions have left much to be desired. Many of the productions have been marred by sensational advertising, exaggeration, distortion, overemphasis of unimportant details and the inevitable love interest. In order to avoid this, the American Committee on Maternal Welfare assumed complete charge of production and distribution of "The Birth of a Baby." They were able to do this because of a gift from Meade Johnson and Company, which defrayed the expenses of making the picture, and an arrangement with a moving picture organization for distribution in an ethical way. The company is under contract to carry out rigid provision in regard to advertising and exhibition. The picture cannot be shown with any other picture which might be objectionable.

The first public showing in the United States was made in Minneapolis where it has just finished a run of three weeks. It was witnessed by 85,524 individuals. As the majority of those who saw it were between fifteen and forty-five years of age, it apparently reached one-third the population of Minneapolis in this age group. Before public exhibition it had been endorsed by the Minnesota State Medical Association, Hennepin County Medical Society, Ramsey County

Medical Society, and the Minnesota State Association of Obstetricians and Gynecologists. Early in December, 1937, it was seen at Northrop Memorial Auditorium, University of Minnesota, by a crowd of more than 4,000 members of the medical, nursing and allied professions. This audience voted 98 per cent in favor of public exhibition.

The story is simply told. A young married woman tells her husband's mother that she thinks she is pregnant. She is advised to consult a physician at once. The audience witnesses her prenatal care through a series of examinations, sympathetic explanations, illustrated charts, and animated drawings. For contrast, a woman who desires an abortion, an inconsiderate husband of a pregnant woman who had borne many children, and a patient with toxemia who did not consult her physician, are seen. The climax of the educational picture is a carefully screened view of the final stage of birth. This is such a logical conclusion that it does not offend anyone.

The audiences in Minneapolis reacted in a wholesome fashion. Sensation seekers were disappointed, as the film is not a sex picture. There was no age limit at the box office which enabled families to come together. High school students were admitted without question as sex is developing during this age period. Many parents wisely concluded that it was much better for their children to get reliable information in a much better way than they were able to give it. If the children seemed too young, their parents were called to learn their wishes in the matter. During the entire three weeks' exhibition of the picture, no complaints were received. On the contrary, many people went out of their way to thank those responsible for its production.

In some states the film has met with official disapproval. When civic officials realize the value of wholesome information on prenatal care, the film will undoubtedly be shown. In 1936, 12,000 mothers died in childbirth in the United States, and 70,000 babies died between birth and one month of age. This is a desperate situation which should be corrected if possible. Ordinary educational channels have been tried without apparent success. The film brings the message home to those who need it most as it attracts mainly younger people of childbearing age. Much of the confusion in regard to the picture has been due to misunderstanding and misinformation. The public response in Minneapolis apparently indicates that much immediate good will come from the picture. As time goes on its effect will be more noticeable since all educational efforts are cumulative.

The success of the public exhibition of "The Birth of a Baby" in Minneapolis was due to careful preparation and sympathetic coöperation of interested groups. The good taste displayed by the American Committee on Maternal Welfare in producing and marketing this picture is worthy of notice. The wholesome way in which it was received is an indication that our people are ready for the proper type of health instruction. It is a picture which provokes reverence and veneration for motherhood. The medical profession has insisted on its right to leadership in health education. The film "The Birth of a Baby" provides them with excellent material to meet the public's demand for ways and means to lower the maternal and infant mortality rates in our country. W. A. O'B.

Minnesota Public Health Campaign

"TUBERCULOSIS Undiscovered Endangers You," is the slogan for the annual, spring, educational campaign to promote the early diagnosis of tuberculosis, sponsored in the state by the Minnesota Public Health Association.

The campaign will be carried on through the distribution of literature and the display of posters stressing the effect of tuberculosis on You —the Individual; You—the Family; and You—the Community.

The great need for educational work toward early diagnosis is brought out in the last annual report of Minnesota Tuberculosis Sanatoria issued by the Division of Tuberculosis, State Board of Control. The report states:

"Sanatorium superintendents are still confronted with a serious obstacle, in giving adequate treatment, due to the fact that the majority of cases admitted to the sanatoria are advanced cases of tuberculosis. In 1935, 10 per cent of the cases admitted were early cases; in 1936, 13 per cent were early cases. There is slight improvement, which is in the right direction, in the number of early cases admitted. However, nearly 90 per cent of the patients who come in are in an advanced stage of the disease, which is very difficult to arrest in most instances and requires prolonged periods of hospitalization and long periods of convalescence after discharge from the sanatorium."

MEDICAL ECONOMICS

Future of Medicine

The importance of the American Medical Association survey of medical care in the United States cannot be over-stated.

It is up to every physician, through his county society, to furnish data requested and to coöperate in every respect with this survey.

The Minnesota State Medical Association is aware that the survey, to be of value, must be accurate and complete and will do everything in its power to make it so.

Instructions and plans will be available soon to all county officers. In the meantime committees should be appointed by every county society to carry on this work.

Action in Minnesota

"The technical committee on medical care, without mentioning 'socialized medicine,' tonight informed President Roosevelt that the effective distribution and use of health and medical services requires a national plan for economic application of our resources in maintaining and improving health."

This paragraph is quoted from a United Press dispatch printed February 26, in the *Minneapolis Journal.*

The committee mentioned is said to be an interdepartmental committee set up by the President to coördinate health and welfare activities.

Possibly one-half the population is unable to pay for medical services, the committee estimated in this newspaper report of its study submitted to the Administration; and "health and sickness services must be made more extensively available through measures that will lighten the . . . costs."

The importance of the American Medical Association study mentioned above in these columns is clear. It is clear also, that the study must be started promptly and pursued vigorously in every quarter of the United States.

Not even lack of funds can prevent damaging action by Congress or the legislatures on the basis of such alarmist reports, unless a sane, comprehensive and absolutely unassailable study of fact can also be put in the hands of the President and Congressional leaders *before* and *not after* laws have been passed.

Study outlines and blanks for the study have already been printed and are in the hands of state medical societies.

It remains now for each society to see the acute need and go to work. A meeting of the Committee on Medical Economics has been called by Chairman W. F. Braasch (also chairman of the Advisory Committee of the American Medical Association for this study) for April 3 in Saint Paul. Every effort will be made to make a prompt, accurate and honest study in Minnesota.

Replying to *Survey Graphic*

A series of articles on the English panel system of medicine have appeared in the last four issues of Survey Graphic. Like so many articles appearing in magazines of this type, they are inexact and biased and contain many superficial observations and half truths. However, they fulfill the mission for which they were intended in attracting a misguided and uninformed public. The purport of these articles is to emphasize that medical care in America is in crying need of reform and that it is much inferior to that given the lower economic group in England. The articles are written by a young physician just out of his medical school in collaboration with his wife, a social worker whose observations apparently form the bulk of the contributions. The authors were sent to England for this purpose, with funds given them by a social welfare organization.

Might Spoil Story

Typical of writers of this kind, no attempt was made to obtain the wealth of data concerning the actual working of the panel system which has been accumulated over the course of years by various American investigators. Such data could have been procured for the asking right in Chicago, at the headquarters of the American Medical Association—but they would, of course, have spoiled the articles.

To the average layman who might read these articles, the case would seem to be closed and proven. One might easily infer from some of the statements made that the only reason socialized medicine has not been instituted in this country is because of opposition from a group of retroactive, narrow-minded officials at the headquarters of the American Medical Association. It would also be inferred that the physicians who compose the A.M.A. are ignorant of the results and the workings of the panel system, have no ideas of their own, and stand dumbly by while the aforesaid officials tell them what to do.

They Do Not Know

The authors apparently do not know that many members of the American medical profession have either personally studied the panel system, discussed the matter fully with various types of English physicians, or have heard innumerable arguments on both sides of the question, so that they are able to form a fair idea of the situation for themselves.

The main argument set forth in favor of the panel system is the fact that most of the English laborers on the panel who were interviewed are satisfied with the medical treatment received. It should be remembered that prior to the establishment of the panel system the laborer had little or no medical care whatever, so that the treatment he receives now is undoubtedly, by comparison, a great improvement. Whether or not such standards of medical care would equal that received by the American laboring man is open to question.

System Admitted Incomplete

The authors admit that the panel system is incomplete in its scope and that the cost of laboratory diagnosis, examination and treatment by specialists, special medication, hospital fees, nursing care and surgery is all extra. These items, of course, are what constitute the bulk of the cost of medical care and what the poor man has difficulty in paying for. A cursory, superficial diagnosis, together with the peddling of pills, which is apparently regarded as satisfactory medical treatment by the English laborer, is but a fraction of the total medical expense. The authors fail to mention the rapidly increasing cost of even this limited type of medical care in the English panel system, as well as the mounting expense of administration and the increase in insurance benefits.

Closing Their Eyes to Inefficiency

In the opening sentences of the first article the authors try to illustrate the difference between conditions which would obtain between governmental medicine in England and the United States. They cite the neglect of a public charge who falls on the street in an epileptic fit in Chicago, and compare it with the efficient care which the patient would have received from governmental health authorities in London. They seem to overlook the fact that the fundamental difference in governmental efficiency in England and America would be sufficient to make a similar system of health impractical and unsatisfactory in this country. With the idealism of youth and inexperience, they close their eyes to the possibility of bureaucratic or political control of American medicine, which undoubtedly would make the practice of medicine in this country an unbearable and inefficient system. The advantages of personal incentive and individual initiative, which have made American medicine what it is today, do not seem to be of paramount importance in their eyes. Another practical consideration which they seem to have overlooked is the fact that the cost of administering and conducting health insurance of this kind in our country would be so many times greater that even our vast national wealth would soon be depleted.

Impossible to Compare

The economic conditions, the standards of medical care, and the political situation in this country are so different from those in England that it is impossible to compare the medical situation in the two countries. American medicine will have to work out its own salvation. Much progress has already been made by individual units of organized medicine. The American

Medical Association is at present making a nation-wide survey of the exact needs for medical care and most of us believe that American medicine can be trusted to work out a plan which will prove best for our country's needs.

With County Society Officials

The County Officers' Meeting affords the best opportunity of the year for county officers to compare notes, air grievances, get assistance.

More than eighty county officers, state officers and members took advantage of it at the 1938 session in Saint Paul, February 26. Proceedings and discussions are briefly reflected in the following highlights of the program.†

J. M. Hayes, Minneapolis, president of the Minnesota State Medical Association: On the basis of a recently conducted survey we may congratulate ourselves on Minnesota's system for handling medical relief. The plan is satisfactory in the majority of counties, a state of affairs which is in striking contrast to many other states where the right to choice of physician on the part of the relief patient is not recognized in the law. Fees for medical relief are unsatisfactory in some instances and require further negotiations between physicians and local county welfare boards for a better adjustment in others. The right of the patient to his choice of doctor is generally recognized, however, with only a few conspicuous exceptions where other difficulties exist also to cloud the issue.

For Revised Constitutions

J. C. Hultkrans, Minneapolis: Every county society should review its constitution with a view to bringing it into conformity with present needs. A few societies are without written constitutions; this lack should be remedied at once. Disciplinary problems and questions arising out of requirements for admission to membership demand a written constitution for settlement. The state association *cannot* determine for the county society who shall and who shall not be admitted to membership. That is the most important single function of the county or district society.

Gordon C. MacRae, Duluth: The St. Louis County Society revised its constitution recently; but has had to amend it since the revision. The new constitution provides for a president-elect who serves on an advisory committee for one

†The paper by T. V. McDavitt, American Medical Association, is printed in full elsewhere in this issue. The interesting address by Attorney General W. S. Ervin on the duties of his office is not included in this report.

President's Message

The recent action of the Board of Trustees of the American Medical Association in instituting the study, by state and county medical societies, of the prevailing need for medical and preventive medical services where such may be insufficient or inavailable, seems very timely.

This body occupies the key position for the supervision of such a study. Many other organizations with lofty ideals but equipped with improper armamentaria have attempted somewhat similar studies. No one can deny the usefulness of any of these studies. We may not like them nor agree with them. They may have done nothing but force out into the open controversial subjects. They may have done nothing but put us in the light as others see us. They may have uncovered only minor deficiencies in the practice of medicine. But we must admit they have aroused the medical profession to action. The profession must prove that it still maintains the high ideals handed down to it by our predecessors. It must prove that it still is true to the precedent long established. Probably no profession or group can look to a more favorable precedent than can the medical profession. Our knowledge and facts have been gained mostly from the work of those who have gone before us. A very superficial study readily reveals the marked scientific advancement in the recent past. Sometimes in our struggle to reach our goal in the more important side of medical practice, as well as in any other walk of life, we are likely to overlook other quite essential factors. No doubt, the practicing physician has to some extent, in the past, overlooked preventive medicine. The study of the relation of the practice of medicine to our general social program, especially from the economic side, has been left largely to those outside our profession.

These surveys and investigations of outside organizations at least serve to make us aware of these deficiencies. They serve to arouse us to the fact that we must devote more attention to these factors or allow those not so well trained to take charge of these angles of practical and preventive medicine. This study suggested by the National Board of Trustees should supplant all other medical surveys in the state. While much of the information will necessarily be only approximate, yet it is not conceivable that any other organization can obtain more definite information.

This study should result in giving us a fair estimate of the proportion of indigent to pay cases; how and where they are being cared for and the efficiency of our preventive medical program. Possibly, also, it will serve to eliminate any duplication of effort, either in the medical care or our preventive medical program.

J. M. Hayes, M.D.

year previous to taking office. An amendment providing for a nominating committee (to replace nominations from the floor) is now in process of passage. Balloting is done by mail in advance of our annual meeting.

Unsung Physicians

M. C. Piper, Rochester: For the sake of adequate records; for the sake of medical history; for the sake of the unsung doctor about whom, otherwise, little will be known when his family and friends are gone, the new application blanks should be filled in by members and applicants to membership alike. The new blanks call for a minimum of genealogical and biographical data; but they will serve as the basis for a general biographical file in the State Office. This data should be extended by some regular system such as a detailed questionnaire sent to all members each five years. The Woman's Auxiliary could help (see "The Council Meets," page 282) both by clipping information in publications and by actually interviewing members to secure the important data.

Health Records Included

These records might include not only scientific accomplishments, and progress but civic interests, hobbies, recreations. Also they should contain information concerning physical condition and general health. The large number of doctors who die prematurely of heart disease points to the importance of securing regular health records of many physicians over a long period of time.

Physicians did not object to filling out repeated records in the years of their preparation for practice. They should not object to keeping a regular record of their progress in life.

G. H. Olds, Waseca: The county secretary could keep track of his members, act as their agent, to some extent, in keeping a record of achievement.

W. F. Wilson, Lake City: We should apologize for having started so late this effort to keep accurate biographical records of all our members.

Informal Meetings

George Earl, Saint Paul: Our relations with the other professional groups who are concerned in the care of the sick are important and should be as close and friendly as possible. They should not take the form of a formal interprofessional organization, however, since the interests and views of one group will not always be identical with others. An occasional general interprofessional meeting is highly advisable in every community. These large meetings should be supplemented by separate meetings between doctors and the separate groups, such as nurses, hospital administrators, technicians. Real progress has been made by the state Committee on Interprofessional Relationships using this method. Small informal discussion meetings serve to iron out mutual problems, advance mutual understanding.

J. N. Libert, Saint Cloud: County interprofessional meetings serve excellently to foster cooperation in worthwhile community projects.

L. H. Flancher, Lake Park: In Iowa, there is a formal interprofessional organization comprising doctors, dentists, druggists, veterinarians, nurses. According to Mr. W. L. Strunk who spoke to our society on the subject the organization has created better feeling between all groups and has fostered public health education. Legislation is acted upon by the groups separately and the organization as a whole is kept out of politics.

(Note: The Council recently voted against a similar organization in Minnesota.)

A. M. A. Survey

C. B. Wright, Minneapolis: Many surveys of medical care have been made in this country. Often they have been made by laymen and they have failed to present an accurate picture of the situation. The American Medical Association, the American Public Health Association and the United States Public Health Service, finding all these surveys unsatisfactory from one point of view or another, recently decided to make a new and comprehensive survey of medical care and health problems all over the country.

They agreed that there is just one way to get at the facts: that is through the local medical societies in every county and district in the United States.

These organizations believe also that care of the sick is a local problem; that any changes in the plan of handling the problem should be under local control.

For an Honest Study

They have constantly opposed any bureaucratic system in Washington or anywhere else which

permits lay officials to come between patient and doctor.

The first step then, is to make an honest and exhaustive survey with the coöperation of every county society in Minnesota and throughout the United States.

Armed with facts we can then go to Washington and say: These are the conditions in the United States and here are our recommendations based upon them.

It has been reported that some thirty to sixty per cent of our people are not getting medical care because they have no money to pay for it. We as doctors know that a large percentage of people do not get medical care because they do not want medical care whether they have money or not. With this survey we hope to get a real picture of the problem in America and analyze it sanely.

Emphasis on "Medical Indigent"

The interest in this survey will center among the so-called "medically indigent" more than upon definitely indigent. There is no doubt in the minds of anyone about the need for outside help in the care of the indigent. The question of medical care for low income groups on the other hand, is the subject of much difference of opinion and misinformation. It is to clarify the situation with respect to these groups and to determine upon plans suited to individual localities if they are needed that the American Medical Association has embarked upon this study.

A statistician and other expert assistance has been added for purposes of this study to the Bureau of Economics of which Dr. R. G. Leland is director. An advisory committee of representative persons from all over the country has been appointed to guide the bureau. The chairman of this committee is Dr. W. F. Braasch, Rochester, chairman of our Committee on Medical Economics. Dr. A. J. Chesley, secretary of the Minnesota Department of Health, is a member of the committee.

The Board of Trustees is determined to make this study complete and significant. They mean business. It remains now for our county societies to help them.

Mr. C. R. Carlgren, Saint Paul, Chairman, State Board of Control: It is important for the future of this state and nation and for the future of civilization, I believe, that socialists and economists should be as effective in their own fields as the medical profession has been in its special field.

Personally, I cannot imagine a society so benevolent or so completely regimented that individual initiative can be eliminated. I firmly believe that we must plan our social order on a basis which allows freedom of initiative to the capable individual.

In the Right Direction

I should like to express to the organization of physicians our appreciation for the fine coöperation and the constructive suggestions given our department. It is my belief that in our Minnesota welfare program, at least, we are proceeding along sane and sound lines of development. The enactment of the County Welfare Board legislation last year was a tremendous step in the right direction because it retains to the individual county local responsibility and initiative.

There has been a tremendous increase in the appropriation to the State Board of Control; but it is chiefly due to the new social security activity which has placed Old Age Assistance, Aid to Dependent Children, Aid to the Blind, Services to Crippled Children under the direction of the Board's Division of Public Assistance. A little more than one out of every three persons of 65 or over in Minnesota is receiving Old Age Assistance.

New Hospital

The increase in the populations of our state institutions has been rather staggering in the last few years, especially in the hospitals for mental ailments. The seventh institution for the mentally ill with a capacity of 200 beds has just been completed at Moose Lake and, I believe, with the leveling off in commitments that seems to be going on now, it should be a long time before Minnesota will be obliged to add any more beds of this type.

There has been very little increase, since the so-called depression, in the correctional institutions. The programs for these institutions is important and the best possible program is the most economical one in the long run. Our training schools at Red Wing, for boys, and at Sauk Center, for girls, are purely training schools. The inmates are of a normal mental

level, and for the most part, they have been more sinned against than sinning. Out of 250 paroled from Red Wing last year, seventy-four had no parents and almost none of the rest have normal home conditions. We have arranged a fine vocational program for these institutions and we now have fine medical care for them. At Red Wing this care is furnished by two local Red Wing clinics.

Qualified Staff

The penal institution for men is self-supporting by the work of the inmate population and the industries established have been of benefit to the farmers of the state. The inmates retain one-third of what they earn and two-thirds goes to their families. Those who have no families retain the whole amount and some are making considerable savings.

I contend that we cannot have proper correctional or disciplinary institutions without a properly qualified staff to participate in every part of the program. That means that we must have vocational experts, qualified medical men, psychologists and psychiatrists to guide in the improvement of mental as well as physical condition of our wards.

J. F. DuBois, Sauk Center, Secretary, State Board of Medical Examiners: The title of this paper—"The Public's Basic Science Law"—is used with a purpose. The Basic Science Law is a Public Health Law, for the public and not for the physicians. In fact, all of the medical laws on our statutes since the territorial days have been placed there for the benefit of the public and the sooner physicians make this fact known, the sooner our legislative problems will be reduced.

All the basic science law tries to do is to raise the standards of all the people caring for the sick. Can any of you think of a more altruistic law than that? Of necessity, it has curtailed cultists; but until cultists are adequately trained, they should be curtailed.

In the six years prior to 1938, Minnesota averaged 39 new chiropractors a year and in ten years under the basic science law we have averaged 1.4 per year. A good many states are now asking for Minnesota's set-up and wanting to know how we got it.

For a Strong Association

That brings me to you secretaries, as representatives of the county societies. Go back to your societies and insist that they back the state in the State Association's program.

In order to have a strong state association we must have close harmony with the county associations just as, if we are to have a strong American Medical Association, we must have strong state associations. Keep your county societies up to full strength. That is the first step to a strong state and national association.

A. J. Chesley, Executive Secretary, Minnesota Department of Health: There were 2,055 deaths from all forms of pneumonia in Minnesota in 1937. We estimate that approximately half of these deaths could have been avoided by use of the serum treatment; and we hope to have sufficient funds to provide serum for every case that needs it. In 1937, 662 specimens were typed; in 1938 to date (January to February 26) 361 specimens have been typed.

There are many details still to be worked out in our pneumonia program in Minnesota. One important phase of the program, the educational phase, will be helped, we believe, by showing with approval of the medical association, the pneumonia film made by the Metropolitan Life Insurance Company and the United States Public Health Service in public theaters.

(The film, a talking picture, shows the family doctor called out in the night to attend a mother, stricken with pneumonia. The sputum is promptly typed, serum treatment is given and the mother recovers. A trailer with information about the pneumonia program in Minnesota is to be added to the film. The Council approved the film.)

Successful Meeting

R. A. Burns, Saint Paul: From 12,000 to 15,000 persons in Saint Paul heard the talks on syphilis given by members of the Ramsey County Medical Society in the course of the education campaign carried on by the Junior Chamber of Commerce, last fall, in coöperation with the society.

The project was proposed to the society by the junior association and the association took care of all arrangements for meetings. Preparation and selection of speakers was turned over to the Society's Speakers' Bureau. Forty or

fifty members responded to the call for volunteers to participate. These volunteers met weekly, discussed material for their talks, submitted specimen speeches. By the time the campaign arrangements were all made, some 35 to 40 talks had been prepared, approved and typewritten. Both speakers and audiences were enthusiastic about the success of the campaign. Requests are still coming in for talks and engagements are booked up, now, until April.

The campaign began very fortunately with a large luncheon meeting addressed by Dr. Morris Fishbein. Everything went with remarkable smoothness. The Speakers' Bureau received considerable publicity and the demand for medical speakers on all subjects has increased.

We now have the organization, experience and machinery to undertake other public health campaigns as they may be needed in Saint Paul.

H. E. Hilleboe, Saint Paul: There are approximately 1,000,000 children under twenty-one years of age in Minnesota and there are records in the State Board of Control at the present time of approximately 9,000 crippled children among them, the majority of whom are unable to pay for private medical care.

With Medical Advice

The State Board of Control is continuing to hospitalize a certain number of crippled children in private hospitals, to be cared for by private orthopedic surgeons. This will continue as long as there are waiting lists at the public hospitals in Minnesota. The orthopedic surgeons are paid for this service on a fee basis which was set up by the Minnesota-Dakota Orthopedic Club. For the year ending June 30, 1937, 20.5 per cent of our total budget of $82,847.36 was paid out for physicians' fees and 42.8 per cent for hospital costs.

The majority of the members of the advisory committee for our service are eminent physicians of our state and it may be said, definitely, that the program is being carried out according to the most ethical standards of medical care.

Mrs. Harlow Hanson, Minneapolis, State Commander Women's Field Army: The Women's Field Army was created to fill the need for a connecting link so far as education is concerned, between the medical profession and the lay public. There has been no lag in the scientific attack on cancer, certainly, and yet, there are still three times as many deaths from cancer as from tuberculosis. I asked the doctors why and they told me, "We think because we do not see the patient soon enough."

Want to be of Use

I have talked to the women in the women's clubs and I find that fear is the principal reason why women hesitate to consult a doctor early about symptoms that might mean cancer. That fear has its source in ignorance. When women have an opportunity to learn the scientific facts about cancer the fear lessens. Intelligent women will listen when we tell them that there is a cure for early cancer; that there are now 25,000 cases on record with the American Surgical Society showing five-year cures for cancer. I am convinced that the death rate from cancer can be cut if we can reach the women with this message. The Women's Field Army is under the direction of the medical profession. We want to be of use to the doctor and we welcome your suggestions.

W. A. O'Brien, University of Minnesota: To date, ten postgraduate medical institutes have been held in a little more than a year at the Center for Continuation Study with a total attendance of 256 physicians. There has been a total of 252 men on the teaching staff of the institutes. The courses have included sixty hours of instruction and 400 hours of intensive clinical and practical work. Thirty-two members of our faculty have come from the full-time teaching staff of the University; 115 from the part-time staff; twenty-four from the Mayo Clinic; sixteen from elsewhere in the state and three from out of the state. Students have come from Minnesota, North Dakota, Wisconsin, Iowa, Montana, California, Nebraska, Persia, China. Of the Minnesota men, twenty-one were from the twin cities, four from Duluth, 101 from elsewhere in the state. It is interesting to note that 40 per cent were in the age period between thirty-five and forty.

E. C. Hartley, Saint Paul: The so-called "Refresher Course," the name of which is going to be changed to something like "postgraduate study course," has just completed its first year. Last year there were courses in six centers throughout the state held at intervals over a period of six weeks. Average attendance ranged from nineteen to thirty-seven.

This spring the course will be given in eight centers and it will last one full day, only. We are picking out instruction centers and making our plans in consultation with the office of the State Medical Association. We learned a great deal last year and hope to learn more this year to the end that these courses may justify the expenditure made for them out of social security funds.

The Council Meets

New Committee

Further evidence of the close and friendly relationship between the Division of Public Assistance and the State Association—a new committee has been appointed by the Council to confer informally with division officials. Many difficulties are encountered by these officials in interpretation of regulations involving health and physical condition. For help, they requested appointment of the medical committee. Dr. A. W. Adson, chairman, Dr. T. H. Sweetser, Dr. George Earl and Dr. J. M. Hayes (ex-officio) will serve.

Transients Again

A new survey of medical needs of transients is to be made in Minneapolis by the United States Public Health Service, Dr. Hayes reported to the Council. Nurses and social workers will question the transients.

Continuous After-Care

Tuberculous patients of state and county institutions will have continuous after-care and supervision if the plan reported to the Council for approval by Dr. H. E. Hilleboe works out as outlined.

Each patient will be reported to his family doctor at home a month before he leaves the sanatorium. The doctor will have all the case history and the recommendations for future care made by the sanatorium superintendent so that there will be no break in medical supervision. At the same time, if necessary, the relief office will receive an advance notice of the return of the patient to his home. If relief is needed, the worker can make necessary arrangements, visit the home and see that necessities of life are provided. The Council approved the plan.

Community Doctor?

Some of the residents of Puposky and the Pleasant Valley believe they need a doctor nearer than Bemidji medical men. They have written to the State Office for advice and assistance.

In 1934 a careful study was made by the Committee to Study Medical Care in Isolated Communities under President Savage's chairmanship. It was found, then, that roads were good and doctors were available. The greatest need appeared to be for public health education to persuade people to seek attention early.

The new complaint was discussed by the Council and referred for study to Beltrami county medical men with the suggestion that any plan for retaining a government doctor be discouraged as unwise and unnecessary.

Aid from the Auxiliary

The suggestion by officers of the Women's Auxiliary that Auxiliary members in Minnesota be asked to follow the lead of Pennsylvania women and clip all local papers carefully for news with any bearing upon doctors or medicine, was applauded by the Council.

Such clippings will be useful to keep up the biographical file on members; to keep committee chairmen informed on lay opinion; and to check use of legitimate newspaper material on health and medicine.

The aid of the women will be accepted with thanks.

Disposing of Samples

Many philanthropic organizations petition doctors for samples from pharmaceutical houses to distribute to their clients. The result is often the administration of remedies to the sick by unqualified if well intentioned lay persons. This practice was disapproved by the Council and should be discouraged. It was suggested that physicians save their samples to administer at their discretion to their own needy patients.

Rehabilitating Unemployables

In West Virginia the State Medical Association is directing a profitable program of rehabilitating otherwise unemployable relief clients and so removing them from relief rolls (See March issue, page 197). The program was outlined in detail to the Council and referred by that body to the Committee on Low Income and Indigent

Problems for study with a view to the possibility of a similar project in Minnesota.

Protest

There are a few quirks in federal regulations that work hardships upon recipients of Social Security Aids and upon physicians also. Members of the Council discussed them, suggested that further inquiry be made of the American Medical Association as to the origin of the regulations and the advisability of protesting them.

One is the regulation of the Comptroller General which makes it impossible to budget for recipients of Old Age Assistance except on a current monthly basis. Another is the regulation which makes it impossible to pay physicians for initial examinations for eligibility required for recipients of some other Aids. The question of failure to pay physicians who care for the needy in their final illnesses was also discussed in view of the fact that undertakers' funds are provided.

Memorial Fund Complete

The final $80.00 needed to make the $2,000 goal set for the Herman M. Johnson Memorial Fund was subscribed by the Council members. The fund will now be invested according to the resolution passed by the House of Delegates and only interest will be used for the lectures on medical economics that will bear his name.

The first lecture in the annual lectureship will be given by Governor Benson Friday, July 1, in connection with the 85th annual meeting in Duluth.

Facts and Figures

A few copies of a pamphlet called "Facts and Figures on Medical Relief in Minnesota" are still available at the state office.

This pamphlet was prepared for the benefit of officers and contact committeemen of county and district societies and contains the latest available information on welfare and relief services in each county, also on the funds spent for these services. There is also a map showing how medical care for relief clients is handled in virtually every county in the state.

The material has proved to be of such interest to others besides the county society officials that Washington, Chicago and some of the official agencies are rapidly exhausting the supply.

There is information, in the pamphlet, conveniently arranged for comparison and study that cannot be secured in this form from any official source of fact and figures. For this reason anyone who has a special interest in welfare and relief matters from the medical point in Minnesota should see a copy. Physicians who attended the County Officers' Meeting in Saint Paul have copies and will lend them, perhaps, since only a handful still remain at headquarters.

Sound Public Policy

Monthly Editorial Prepared by the Medical Advisory Committee

Today, as never before, professional groups are being scrutinized by lay people, and every opportunity is taken to deride and break down the time-tested ethics of these groups.

Your Medical Advisory Committee believes that perhaps we, the members of the medical profession, are at fault to a great extent in this loss of confidence, that the dignity of our calling is being lost sight of by us in the search for the "pot of gold." Especially is this true when we find doctors testifying in court on a contingent basis, their fees depending on the winning or losing of the case at hand. Will their testimony be unbiased and for the best interest in a court of justic under this arrangement? Does it not bring disrepute on all medical testimony to sell our knowledge for a "mess of pottage"? Why not be honest with ourselves and the lawyers in the case—an honest fee for an honest opinion.

The Principles of Medical Ethics, Article VI, Section 5, reads as follows:

"It is unprofessional for a physician to dispose of his professional attainments or services to any lay body, organization, group or individual, by whatever name called, or however organized, under terms or conditions which permit a direct profit from the fees, salary or compensation received to accrue to the lay body or individual employing him. Such a procedure is beneath the dignity of professional practice, is unfair competition with the profession at large, is harmful alike to the profession of medicine and the welfare of the people, and is against sound public policy."

This means that entangling alignments between doctors and lawyers are against sound public policy, and no member of our association should be guilty of such conduct. Remember, "As ye sow, so shall ye also reap." If we are going to elevate our standing in the eyes of our communities, we must do it ourselves. "Honesty is the best policy" in court as well as in other types of consultation.

Minnesota State Board of Medical Examiners

Minneapolis Quack Sought by Sheriff

Re: State of Minnesota vs. Francis Howard Punchard, Sr., alias J. Francis Clark.

Sheriff John P. Wall of Minneapolis holds an order for the arrest and commitment of Francis Howard Punchard, Sr., alias J. Francis Clark, fifty-eight years of age. On February 17, 1938, the Honorable Arthur W. Selover, Judge of the District Court of Hennepin County, issued an order vacating the stay of sentence previously given Punchard on October 5, 1936, by Judge Leary. Punchard, at that time, was sentenced to six months in the Minneapolis Work House and a stay given him on the condition that he leave the State of Minnesota and remain out of it for a period of not less than five years. Punchard was seen in the Lowry Medical Arts Building, St. Paul, on February 16, 1938, by a representative of the Minnesota State Board of Medical Examiners. He stated at that time that he had been teaching at the Minnesota Chiropractic College, 1824 15th Avenue South, Minneapolis. He was ordered to report to the County Attorney's office the following morning but failed to show up. The order of Judge Selover followed. At the time this article was written the Sheriff's office had been unable to locate Punchard. It has been reported, however, that Punchard was again in the Lowry Medical Arts Building on Monday, February 21.

Punchard is a rather well known quack, having been convicted in Chicago in 1932, on a charge of practicing medicine without a license. He makes rather elaborate representations as to who he is and where he has obtained his education. He has represented himself, on occasion, as being a graduate of Oxford, the University of Maryland, and as having taught at the University of Minnesota. Punchard holds no diploma from any recognized medical school, nor is he licensed to practice medicine anywhere in the United States.

The Medical Board respectfully requests that it be immediately notified by telephone, Cedar 2064, Saint Paul, if Punchard comes to the attention of any members of the medical profession in this state.

Dakota County Janitor Pleads Guilty to Abortion

Re: State of Minnesota vs. Kish.

On March 1, 1938, Frank Kish, forty years of age, entered a plea of guilty to an information charging him with the crime of abortion. The plea of guilty was entered before the Honorable Richard A. Walsh, Judge of the District Court for Ramsey County. After hearing the facts, Judge Walsh sentenced the defendant to a term of eighteen months at hard labor in a state penal institution.

Kish, who stated he was born in 1897 at Coaldale, Virginia, and who has resided in Minnesota since 1916, was arrested on February 24, 1938, following a joint investigation made by the Minnesota State Board of Medical Examiners, the County Attorney's office and the Sheriff's office of Ramsey and Dakota Counties. Kish was employed as a janitor at School District Number 5 of Dakota County. For the past three years he has been performing an occasional criminal abortion, admitting some twenty to twenty-five abortions. Some of these were performed at the school in Dakota County, and others at the homes of the women in Saint Paul. Upon being questioned by Judge Walsh, Kish stated that he had only an eighth grade education and no medical training whatsoever. He used a catheter in his work and in some cases administered ergot. He charged whatever he could get, the fee varying from $5.00 to $30.00 per case. The defendant is married and the father of four children.

List of Physicians Licensed by the Minnesota State Board of Medical Examiners on February 11, 1938

January Examination

Bagley, Charles Miller, Stanford U., M.D., 1937, Duluth, Minn.

Bagwell, John Spurgeon, Jr., Baylor U., M.D., 1936, Rochester, Minn.

Bailey, Allan Archibald, U. of Toronto, M.D., 1935, Rochester, Minn.

Baumgartner, Florian Herman, U. of Minn., M.B., 1937, Saint Paul, Minn.

Caspers, Carl Gerald, U. of Minn., M.B., 1937, Saint Paul, Minn.

Cochrane, Byron Barlow, U. of Minn., M.B., 1937, Saint Paul, Minn.

Code, Charles Frederick, U. of Manitoba, M.D., 1934, Rochester, Minn.

Davis, Luther Forest, U. of Minn., M.B., 1937, Minneapolis, Minn.

Doss, Alexander Keller, Tulane U., M.D., 1934, Rochester, Minn.

Ferris, Deward Olmstead, Queen's U., M.D., 1931, Rochester, Minn.

Fisher, Herbert Calvin, Cornell U., M.D., 1935, Rochester, Minn.

Fitzsimons, William Edmund, U. of Minn., M.B., 1937, Saint Paul, Minn.

Giffin, Herbert Martin, Johns Hopkins, M.D., 1935, Rochester, Minn.

Giffin, Lewis Albee, Harvard U., M.D., 1935, Rochester, Minn.

In Memoriam

George Sheryl Cabot

1899-1937

DR. GEORGE S. CABOT, of Jamestown, North Dakota, died on December 16, 1937, following an emergency operation. Dr. Cabot was associated in practice with his brother Dr. Verne S. Cabot, and his brother-in-law, Dr. Arthur A. Wohlrabe, in Minneapolis, from 1925 until 1935, when he moved to Jamestown.

Born August 2, 1899, in Minneapolis, Dr. Cabot attended the elementary and high schools in Minneapolis and received his M.D. from the University of Minnesota medical school in 1923.

Dr. Cabot was a member of the Hennepin County Medical Society and the Minnesota State Medical Association while residing in Minneapolis, and transferred his membership to the North Dakota State Medical Association upon moving to North Dakota. He was a member of the Alpha Kappa Kappa medical fraternity, and of the Masonic order.

Dr. Cabot is survived by his widow, whose maiden name was Grace McCrum, and two sons, Hugh, aged nine, and Allyn, aged six. Besides a brother, Dr. Verne S. Cabot, and a sister, Mrs. Arthur A. Wohlrabe, both of Minneapolis, Dr. Cabot is survived by another brother, Dr. Clyde N. Cabot of Calgary, Canada.

Joseph Edward Honore Garand

1874-1937

DR. J. E. H. GARAND, for the past forty years a practicing physician of Dayton, Minnesota, passed away on December 12, 1937, at the age of sixty-three, from pneumonia.

Born at Sherbrooke, Quebec, February 14, 1874, Dr. Garand attended local schools and received his medical degree from Laval University, Montreal, where he graduated with honors.

Arriving in Dayton in 1900, Dr. Garand was active in local affairs. At different times he was mayor of Dayton, clerk of the village and a member of the school board.

Dr. Garand is survived by his widow and a daughter, Mrs. Honorine Dupont, of Minneapolis.

The Cornell Cancer Treatment

Recently newspapers contained an announcement to the effect that Dr. Beaumont Cornell of Fort Wayne, Ind., had discovered an amazing treatment for cancer. Briefly the treatment consists of the injection into patients with cancer of a product which he has labeled Anomin and which represents extracts made from the testicular and ovarian tissues of cattle. It was claimed for this new extract that it prevented the formation of metastases, that pain ceased and that tumors liquefied. The only evidence is the unsupported statement of the author. The work is all recent; time is required to determine whether or not cancer is really cured in any patient. The methods of promotion and the publicity associated with the announcement of this method would seem to be wholly outside the usual accepted scientific procedures. (J. A. M. A., Feb. 26, 1938, p. 656.)

OF GENERAL INTEREST

Dr. L. M. Roberts, of Little Falls, has retired after forty-eight years of active practice.

* * *

Dr. V. J. Telford has returned to Litchfield from Denver, and has resumed practice.

* * *

Dr. and Mrs. E. G. Bannick, of Rochester, are moving to Seattle, where they plan to make their home.

* * *

The *Journal of School Health* for March, 1938, announces Dr. Lillian L. Nye's Fellowship in the American School Health Association.

* * *

Dr. W. L. Sibley, formerly located at Rochester, Minnesota, has moved to Roanoke, Virginia, where he is affiliated with the Lewis-Gale Hospital.

* * *

Dr. P. O'Hair, pioneer Waverly physician, celebrated his ninetieth birthday on February 24. He retired from active practice in 1930.

* * *

Dr. and Mrs. Robert J. Hill, formerly of Saint Paul, have moved to Anoka, where Dr. Hill has established his practice.

* * *

Dr. and Mrs. William A. O'Brien, of Saint Paul, are receiving congratulations on the birth of a son, Patrick, born March 17.

* * *

Dr. C. G. Ochsner, of Wabasha, was elected president of the Chamber of Commerce at the organization meeting held recently.

* * *

Dr. and Mrs. L. C. Culligan, Sibley Highway, are receiving congratulations on the birth of a daughter, born March 3.

* * *

Dr. L. B. Wilson, of Rochester, addressed the Hi-Y club there early in March on the subject of "How to Spend Leisure Time."

* * *

Drs. W. E. Johnson and E. W. Wahlberg, of Morgan, have moved into new quarters in the former Farmers and Merchants Bank Building.

* * *

Dr. F. Schleinitz has settled in Avon, where he will engage in the practice of medicine. His office and residence are located in the new hospital building there.

* * *

Dr. Julian F. Du Bois, secretary of the Minnesota State Board of Medical Examiners, was elected vice president of the Federation of State Medical Boards of the United States at its annual meeting held in Chicago in February.

* * *

Dr. F. N. Solsem, of Sacred Heart, has sold his practice to Dr. R. Erickson, a graduate of the Medical School of the University of Minnesota. Dr. Solsem plans to take up graduate work at the Medical School of the University of Colorado, after a visit with his daughter and son-in-law in Denver.

* * *

Dr. S. A. Slater, of Worthington, has been appointed on a national committee of five to study the coordination of federal, state and local programs against tuberculosis, and recommend a workable plan. The appointment was made by Dr. J. A. Myers of Minneapolis, president of the National Tuberculosis Association.

* * *

Dr. W. P. Olson, of the Gaylord Hospital, has announced that his son, Dr. Duane Olson, will soon become associated with him in the conduct of the Gaylord Hospital, and in general practice. Dr. Duane Olson is a graduate of the University of Minnesota and is just completing his internship at General Hospital, Minneapolis.

* * *

Dr. S. A. Forestiere will return to Pine River from New York City about April 1 to take over the St. Matthew Hospital, which he has purchased from Dr. A. J. Button. Dr. Button opened the hospital January 1, 1934, and has operated it since that time. It was first known as the Holman Hospital, but was recently incorporated as St. Matthew Hospital.

* * *

Dr. and Mrs. John S. Lundy of Rochester sailed for Europe late in March. Dr. Lundy expects to visit clinics in Vienna and other medical centers in Germany, France, Switzerland, Holland and England. They will return to Rochester about June 1.

Before sailing, Dr. Lundy will address a meeting of the American Society of Anesthetists in New York, his topic being "Intravenous Barbiturate Anesthesia."

* * *

Dr. and Mrs. P. S. Hench, of Rochester, have sailed for Europe. Dr. Hench attended the meeting of the International Congress on Rheumatism and Hydrology at Oxford, March 26 to 31, and will address the International Conference on Rheumatic Disease which is being held in Bath, England. His topic will be "The Effect of Spontaneous and Induced Jaundice on Rheumatoid Arthritis and Fibrositis."

Dr. Hench will also visit clinics in England and Scotland.

* * *

Dr. Edgar H. Norris, for the past four years a teaching fellow in the Department of Pathology at the University of Minnesota Medical School, during which period he has made a number of important contributions to medical literature, has been appointed Head of the Department and Professor of Pathology in Wayne University College of Medicine, Detroit, Michigan. He will assume his duties in the early fall. Dr. Norris graduated from the University of Minnesota Medical School in 1919. He practiced surgery for a number of years in Saint Paul before devoting himself to Pathology.

MEDICAL BROADCAST FOR APRIL

The Minnesota State Medical Association Morning Health Service.

The Minnesota State Medical Association broadcasts weekly at 9:45 o'clock every Saturday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

April 2—10th Anniversary.
April 9—Arteriosclerosis.
April 16—Glaucoma.
April 23—Brain Tumors.
April 30—Dental Research.

AMERICAN ASSOCIATION FOR THE STUDY OF GOITER

The third international goiter conference will convene in Washington, D. C., September 12 to 14, 1938. English will be the official language, but interpreters will be furnished for papers read in a foreign tongue. Further information may be obtained from Dr. Allen Graham, chairman of the Program Committee, 2020 East 93rd Street, Cleveland, Ohio.

AMERICAN BOARD OF OPHTHALMOLOGY

The American Board of Ophthalmology announces that in 1938 it will hold examinations in San Francisco, June 13, during the American Medical Association meeting; Washington, D. C., October 8, during the American Academy of Ophthalmology and Oto-Laryngology meeting; Oklahoma City, November 14, during the Southern Medical Association meeting.

The American Board of Ophthalmology has established a Preparatory Group of prospective candidates for its certificate. The purpose of this Group is to furnish such information and advice to physicians who are studying or about to study ophthalmology as may render them acceptable for examination and certification after they have fulfilled the necessary requirements. Any graduate or undergraduate of an approved medical school may make application for membership in this Group. Upon acceptance of the application, information will be sent concerning the ethical and educational requirements, and advice to members of the Group will be available through preceptors who are members or associates of the Board. Members of the Group will be required to submit annually a summarized record of their activities.

The fee for membership in the Preparatory Group is ten dollars, but this amount will be deducted from the fifty dollars ultimately required of every candidate for examination and certification. For sufficient reason, a member of the Preparatory Group may be dropped by vote of the Board.

ASSOCIATION OF INDUSTRIAL PHYSICIANS AND SURGEONS

The annual meeting of the Association of Industrial Physicians and Surgeons and Midwest Conference on Occupational Diseases will be held at the Palmer House, Chicago, June 6-9, 1938. The purposes of the organization are minimizing the morbidity and mortality in working people from industrial accidents and diseases, and all physicians and surgeons interested in this phase of preventive medicine are urged to attend. A. G. Park, 540 N. Michigan Avenue, Chicago, is Convention Manager, and is in charge of exhibits.

CITIZENS AID SOCIETY

The Cancer Institute Committee of the University of Minnesota Medical School has announced the 1938 Citizens Aid Society Lecture which will be presented at the Medical School on the evening of Tuesday, April 12. Dr. Edgar Allen of Yale University Medical School will present this Lecture, the title of which will be "Ovarian Hormones in Relation to Female Genital Cancer."

POSTGRADUATE COURSE FOR PHYSICIANS IN OBSTETRICS AND PEDIATRICS

Beginning in May the second state-wide Postgraduate Course for Physicians in Obstetrics and Pediatrics will be given in eight centers throughout the state. This is the course presented through the coöperated efforts of the Minnesota State Medical Association, the Medical School of the University, and the State Department of Health. It is financed by funds coming to the Division of Child Hygiene of the State Department of Health through Society Security appropriations.

The centers and dates for this year are, as follows:

May 4—Crookston
Winona
May 11—Hibbing
Willmar
May 18—Albert Lea
Fergus Falls
May 25—Worthington
Bemidji

The arrangements will be different this year from last. The sessions in each center will last all day, and the entire material will be presented in that one day. There will be four lectures in obstetrics and four in pediatrics given by two obstetricians and two pediatricians. This arrangement was decided upon after considerable discussion in order to meet some of the objections which arose last year. Particularly, that the work extended over too long a period, making it

difficult for the men to arrange for attendance. It was felt by most of those who discussed the question that in general the physician in practice could more readily arrange for one full day away from his office than he could for parts of a number of successive days.

Complete schedules for the course and an outline of the material to be presented will be mailed by Mr. R. R. Rosell, Executive Secretary of the Minnesota State Medical Association, to the physicians in and about the eight centers which have been selected.

RESERVATIONS, STATE MEETING

Hotel reservations for the 85th annual meeting of the Minnesota State Medical Association to be held in Duluth, June 29, 30 and July 1, should be made immediately according to the Committee on Local Arrangements of which Dr. R. J. Moe is chairman.

One of the best programs in the history of the organization has been arranged and an attendance of more than twelve hundred is expected from Minnesota and from surrounding states. Most of those who attend will plan, also, to take advantage of the dates and extend their trips, with their families, until after the Fourth of July holiday.

Several other organizations will be meeting in Duluth at the same time, according to the Committee, and will require accommodations.

Meeting headquarters are at the Hotel Duluth. A list of eight additional hotels has been selected by the committee, however, and excellent accommodations can be secured in any of them. The complete list with rates is printed below. Reservations should be made direct with the hotel chosen.

Hotel	Single	Double
Hotel Duluth, 231 E. Superior St.		
(With Bath)	$3.00 & up	$4.00 & up
Spalding Hotel, 5th Ave. W. & Superior St.		
(Without Bath)	1.50 & up	2.50 & up
(With Bath)	2.50 & up	3.25 & up
Lenox Hotel, 6th Ave. W. & Superior St.		
(Without Bath)	1.50 & up	2.50 & up
(With Bath)	2.25 & up	3.25 & up
Holland Hotel, 11 N. Fifth Ave. W.		
(Without Bath)	1.75 & up	2.75 & up
(With Bath)	2.50 & up	3.50 & up
Lincoln Hotel, 317 W. 2nd St.		
(Without Bath)	1.50 & up	2.50 & up
(With Bath)	1.75 & up	2.75 & up
McKay Hotel. 430 W. 1st St.		
(Without Bath)	1.25 & up	2.00 & up
(With Bath)	1.75 & up	2.75 & up
Cascade Hotel, 101 W. 3rd St.		
(Without Bath)	1.50 & up	2.00 & up

(Without Bath)	1.00 & up	2.00 & up
(With Bath)	2.00 & up	3.00 & up
Hamilton Hotel, 1418 E. Superior St.		
(Without Bath)	1.50 & up	2.00 & up
(With Bath)	2.50 & up	3.50 & up

WABASHA AND WINONA COUNTIES

The seventh annual joint meeting of the Wabasha and Winona County Medical Societies and the thirteenth annual dinner tendered by the Sanatorium Commission to the physicians of the counties served was held at Buena Vista Sanatorium, Wabasha, Minnesota, on Monday evening, March 14. There were thirty-four in attendance, including doctors and four lay members of the Sanatorium Commission.

Dr. H. T. Sherman, president of the Wabasha County Society, officiated as toastmaster. Dr. James M. Hayes, president, and Mr. R. R. Rosell, executive secretary of the State Medical Association, gave talks on the aims and purposes of the State Association. Dr. I. W. Steiner, secretary of the Winona County Society, gave a report on the recent County Officers' Conference in Saint Paul.

The following papers were presented:

"Acute Abdominal Conditions," Dr. James M. Hayes, Minneapolis.

"Diagnosis and Treatment of Primary Carcinoma of the Lung," Dr. Thomas J. Kinsella, Minneapolis.

"Intractable Nasal Hemorrhage, with Report of Case Requiring Ligation of the External Carotid Artery," Dr. George L. Loomis, Winona. Discussion was opened by Dr. Eli E. Christensen, Winona.

WASHINGTON COUNTY

The regular meeting of the Washington County Medical Society was held March 8 with good attendance. The Secretary reported on the County Officers' Meeting and following that there was a discussion on the welfare board's activities.

There was also a report on the Mantoux tests showing that out of 305 pupils only twelve refused to take the test. There were forty-four pupils who were positive reactors, forty-three of whom were x-rayed. One pupil refused. There were also fourteen adults (teachers) tested, with three positives. Three children outside of the school were x-rayed. There was also a report on the vaccination questionnaire which disclosed the fact that quite a number of pupils throughout the grade schools had not been vaccinated.

Dr. E. V. Strand, of Bayport, spoke to the Society about his trip East. He visited the medical centers in Montreal, Boston, New York, Baltimore, and Washington. His experiences were well outlined and told in a manner which was enjoyable to listen to as well as instructive. He also mentioned the up-to-date equipment in the hospitals in these medical centers.

Dangers of Sodium Perborate in the Mouth

The most prominent ingredient used in recent years in dentifrices and mouthwashes for antiseptic purposes is sodium perborate. This has been inspired, no doubt, by its alleged efficiency in combating Vincent's infection. According to the clinical observations recorded in a recent questionnaire study by Isador Hirschfeld, chairman of the Committee on Scientific Investigation of the American Dental Association, perborate may cause (1) painful chemical burns of the oral mucosa (including the gingivæ); (2) less painful or entirely painless burns producing a milky-white discoloration, especially of the marginal gingivæ; (3) an inflamed condition of the oral mucosa, which predisposes the gingivæ and mouth generally to ready abrasion and infection through minimal traumatization, and (4) a form of "hairy tongue" which in some instances causes gagging or irritation of the soft palate and pharynx. Ample examples of the danger of this form of self medication have now been recorded and adequate proof offered. (J. A. M. A., Feb. 5, 1938, p. 445.)

WOMAN'S AUXILIARY

Mrs. J. F. Norman, Crookston, *President*
Mrs. A. A. Passer, Olivia, *Editor*

AN OPEN LETTER TO THE MEMBERS OF THE STATE MEDICAL AUXILIARY

Dear Auxiliary Members:

There are a number of matters which I want to bring to your attention, and I appreciate the privilege of communicating with you through the pages of Minnesota Medicine.

You will be interested to know that the Auxiliary will again show a nice gain in membership this year; at this writing, ten County Auxiliaries have reported a larger membership than in previous years. This is encouraging, for the reason that if the State Auxiliary wishes to continue as a vital reserve force for the Medical Association, it is necessary to grow numerically. The various groups are to be commended for the prompt attention given the payment of dues during March; as a result, the State, in turn, will be in a position to remit dues promptly to the National Auxiliary.

The mid-winter meeting of the Executive Board was held in Minneapolis on January 14 because it was possible for our National President, Mrs. Augustus Kech, to be with us on that day. Mrs. Kech recommended that the Minnesota Auxiliary assist the Medical Society by establishing a Clipping Bureau. Your president placed the matter in the hands of the Medical Advisory Board, and at a meeting of the Council which followed the County Officers' meeting on February 26, the idea was enthusiastically endorsed by the Council which went on record as stating that the Medical Association would accept this service with appreciation. You will have the privilege of deciding definitely about this as a project at the annual meeting; in the meantime, if you are interested, start clipping! Clip everything from your local newspapers which has any reference to medicine or local physicians; editorials are of especial interest. This service will be of great value to the Medical Association and we are hoping it will receive your active coöperation.

Another recommendation which was made by a special committee and adopted at the Board meeting, was to the effect that County Auxiliaries follow the State Constitution, Article X, with reference to delinquent members of said Auxiliaries. Other matters of interest to all the members were discussed at the Board meeting and will be included in the reports at the annual meeting.

The State Meeting will be held in Duluth June 29, 30 and July 1, and the annual business meeting of the Auxiliary will be held on Thursday, June 30. Plans are going forward to make this meeting one of lasting inspiration, and it is not too early for you to make your plans to attend. Duluth is famous as a hostess city and the women of the St. Louis County Auxiliary are busily engaged in making preparations for the meeting. There is talk of a trip on Lake Superior on July 1, so try to have your plans include all three days of the convention. With your assistance and coöperation, the sixteenth annual meeting of the Minnesota State Medical Auxiliary will be a memorable one.

Loretta M. Norman, *President.*

The Vitamin C Content of Commercially Canned Tomato Juice and Other Fruit Juices as Determined by Chemical Titration

The Council on Foods reports that many physicians have inquired about the vitamin C content of canned fruit juices. In order to obtain further information on this point, Dr. E. M. Bailey of the Connecticut Agricultural Experiment Station, New Haven, has supplied comparative data on the cevitamic acid content of Council accepted products by chemical titration. This survey covers all canned fruit juices which, at the time of the examination, were privileged to display the seal of the Council on Foods. The figures show that all brands of the canned fruit juices examined contained appreciable quantities of vitamin C. In terms of the average approximate number of international units of vitamin C per hundred cubic centimeters, the values are: pineapple juice 300, tomato juice 400, grapefruit juice 750, orange juice 900 and lemon juice 1,000. From the figures available, it would appear that canned orange juice is only slightly less potent in vitamin C than the fresh juice from which it is made. Approximately two and one-half volumes of canned tomato juice should be given in order to provide the vitamin C equivalent of one volume of fresh orange juice. If other juices are to be substituted, it is probable that the substitution could be made, other things being equal, on the basis of the vitamin C content. (J. A. M. A., Feb. 26, 1938, p. 650.)

Udga Tablets

The Bureau of Investigation reports that according to a Federal Trade Commission release for May 21, 1937, the Commission ordered Udga, Inc., to cease and desist from representing "through advertisements, circulars or testimonials, or in any other manner, that the product would cure stomach ulcers, gastritis, indigestion, dyspepsia and various other stomach ailments and diseases, including those caused or reputed to be caused by hyperacidity." William Fraser of St. Paul is president of Udga, Inc. Fraser is a voluminous advertiser and, among other advertising devices, publishes *Fraser's News,* a puff sheet devoted to the wonders of Udga Tablets. From Fraser's "Column of Health Comment" we learn: "Years ago, after I left the army . . . Back home in St. Paul, Minn., I learned first hand of a formula developed by a renowned physician for treatment of stomach acidity—that distressing condition so little understood by doctors generally . . ." Nowhere in the Fraser advertising available to the Bureau of Investigation is there any clue that Mr. Fraser has had any training in pharmacy, chemistry, physiology, pathology or therapeutics. According to the government chemists' analysis, each Udga Tablet contained about 9 grains of sodium bicarbonate, about 9 grains of bismuth subnitrate and about 8 grains of magnesium exide. The limited value of these common drugs is well known to every physician. Certainly they are not to be relied on in the indiscriminating and unsupervised treatment of gastric ulcer. (J. A. M. A., August 21, 1937, p. 605.)

Meeting of January 12, 1938

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, January 12, 1938. Dinner was served at 7 o'clock and the meeting was called to order at 8:15 by the president, Dr. R. T. LaVake.

There were fifty-nine members and two guests present.

This being the annual meeting at which the President's address is read, no business was taken up.

DIAPHRAGMATIC HERNIA

E. M. Jones, M.D.
Saint Paul

Dr. E. M. Jones, retiring president, read his address on the above subject, illustrated with lantern slides. He requested that the paper be discussed. (Complete paper to appear later in Minnesota Medicine.)

Abstract

The diagnosis and treatment of diaphragmatic hernia has received increasing attention during the past few years. There is no reason to assume the condition to be more prevalent than heretofore, but rather that improvement in diagnostic methods has made its presence more easily and thus more frequently proven. Development in roentgenological technic, together with accurate clinical observation, has resulted in the placing of diaphragmatic hernia in the list of common conditions.

In 1853, Bowditch reviewed the subject of diaphragmatic hernia and reported a case seen at the Massachusetts General Hospital, observing that earlier writers believed that a wound of the diaphragm was always fatal.

Diaphragmatic herniæ are considered true or false depending on whether or not a sac is present. They are further divided into congenital and acquired, the latter possibly traumatic in origin.

These various types of herniæ are discussed from the standpoint of their occurrence and symptoms presented. Various points are emphasized that will aid in the diagnosis. There is also discussion of the congenital short esophagus and the surgical importance of differentiating it from a diaphragmatic hernia is emphasized.

Reduction of the hernia with repair of the hernial opening is the only means of definitely relieving the symptoms. As long as strangulation does not occur, the presence of abdominal viscera within the chest is not incompatible with life.

Many aspects of the treatment of diaphragmatic hernias are discussed.

Five cases of diaphragmatic hernia that have been operated upon are discussed and lantern slides were shown demonstrating the condition before and after surgical repair. There are three cases of esophageal hiatus hernia and two that are traumatic. Two slides were shown of a congenital diaphragmatic hernia.

In this group of cases three were cured, there was one recurrence and one death.

Discussion

Dr. J. F. Corbett, Minneapolis: I want to congratulate Dr. Jones on his series of cases. It is master surgery and very few of us can point to so many cases. I saw one case that was a potential diaphragmatic hernia. This boy had been shot in the lower part of the left chest and when admitted to the hospital his condition was bad. The most marked symptoms were abdominal, but no fluid could be demonstrated in the abdomen. There was some blood in the chest and there was pain referred to the shoulder. For that reason, by means of an intratracheal positive pressure apparatus, I ventilated the lungs and opened the chest and found one of the most remarkable pictures I have ever seen. The bullet had cut the diaphragm and nothing had gotten into the abdominal cavity. We repaired the defect and, so far as we have been able to learn, he has been in good health since. The blood was what led me to go into the chest cavity. It was from the intercostal arteries. So, the manner of approach was correct but the main reason for selecting this route was fallacious.

Dr. Martin Nordland, Minneapolis: Dr. Jones is to be complimented for his excellent discussion of this interesting subject. In this connection, I thought it might be of interest to report a case of congenital diaphragmatic hernia, recognized by the pediatrician three days after birth and which I operated upon five days after birth. The infant was delivered by the obstetrician by cesarean section.

From the time of birth the patient frequently became cyanotic when nursing and vomited after each feeding. Occasionally the vomitus contained a small amount of blood. The pediatrician noted bizarre sounds in the chest and an x-ray examination on the third day after birth revealed the presence of the entire stomach in the right side of the chest. A diagnosis of diphragmatic hernia was established and an operation was advised. At operation on the fifth day, the stomach was replaced in the abdominal cavity and the diaphragm sutured. The suturing was accomplished with much more ease than in similar hernias in adults. The patient died on the twelfth day from pneumonia. The postmortem examination revealed the stomach had remained in good position in the abdominal cavity.

The case is of interest because of the early diagnosis, the predominating symptoms being cyanosis and vomiting and the positive diagnostic x-ray findings. It is of further interest because the hernia occurred on the right side of the diaphragm. Statistics reveal that only about 22 per cent of diaphragmatic hernias occur on this side. It has been frequently noted that infants with diaphragmatic hernias have other congenital deformities. This case had a large inguinal hernia, bilateral club-feet and a rather marked hypertrophic pyloric stenosis.

Dr. O. H. Wangensteen, University of Minnesota: Dr. Jones pointed out that internal hernias, of which diaphragmatic hernia is a type, become obstructed but do not strangulate as readily as do external hernias. This comes about because the structures about the

apertures through which the intestine may herniate are not so unyielding as in external hernias, where ligaments like Poupart's or Gimbernat's cause obstruction and strangulation simultaneously. Strangulation, of course, does attend neglected obstructed diaphragmatic hernias. It is because of this lesser tendency to strangulation in diaphragmatic hernia that a short trial with suction applied to an inlying duodenal tube is in order before recourse is had to surgery. The gaseous distension and fluid retention in the stomach can be relieved usually by this means and reposition of the abdominal viscera herniated into the thorax can be then undertaken with less risk to the patient. A preliminary decompression of the colon as advocated by Truesdale is to be done only in those instances in which a "scout" x-ray film of the abdomen indicates that the colon is considerably distended. In diaphragmatic hernias of traumatic origin in which a portion of the colon becomes engaged and obstructed in the diaphragmatic aperture, Truesdale's suggestion of preliminary cecostomy is a good one. For, as has been repeatedly pointed out in recent years in the literature of bowel obstruction, the ileocecal valve and sphincter behave as a check-valve, permitting the entry of fluid and gas from the proximal reaches of the gut, but regurgitation of content from the obstructed colon into the ileum is precluded by the ileocecal valve. If such an obstruction goes unrelieved for long, perforation of the distended colon is bound to happen.

The para-esophageal hernias of which Dr. Jones spoke at length are, of course, not so likely to become obstructed. Occasionally, however, volvulus of the stomach may occur in an unusually large para-esophageal hernia. Such an occurrence has once come under my attention. In the main, however, obstruction or strangulation in para-esophageal hernias is decidely unusual. It is difficult to escape the impression that surgeons have attacked these hernias with greater enthusiasm than they are justified in doing. In a few cases in which the roentgenologist made the diagnosis of para-esophageal hernia with confidence, I have been unable to demonstrate to my own satisfaction at operation that a hernia was actually present. After operation, the roentgenologist declares that the hernia is no longer present, and again re-examination after several months fails to disclose evidence of the hernia. Yet the patient continues to complain of the same symptoms as he did when the alleged hernia was discovered on roentgen examination. The large para-esophageal hernias, which Dr. Jones spoke of, should be repaired surgically when they cause symptoms and the physical status of the patient warrants undertaking operation. Many of you are undoubtedly familiar with the controversy which Prof. Cauerbruch and his erstwhile roentgenologist Berg, now of Hamburg, had over these so-called "Epiphrenische Glocken." Sauerbruch steadfastly maintained that these supra-diaphragmatic shadows of gastric mucosa which roentgenologists observed and described as para-esophageal hernias were often not hernias at all. My own experience with some of these is very much like that of Prof. Sauerbruch, and I would suggest that surgeons exercise some restraint in operating upon all para-esophageal hernias diagnosed as such by roentgenologists.

I had an interesting experience a short time ago with a congenital pleuro-peritoneal hiatus hernia in a man of twenty-seven (University Hospital No. 662347), which may interest you. Until he engaged in a wrestling bout in April, 1937, he had no symptoms referable to the hernia. The application of the "scissors-hold" to the abdomen caused him to become dyspneic and to have abdominal pain accompanied by vomiting. The seizure was soon over and he was again quite well until midsummer when a similar attack came on without apparent provocation. The spell for which he was finally hospitalized in October, 1937, came on during the night and he was brought to the hospital with the picture of an acute intestinal obstruction. A scout film disclosed the presence of the stomach in the thorax. The left diaphragm could not be identified roentgenologically and it was suggested that the patient might have an eventration of the diaphragm—a suggestion which could not account adequately for the obstruction. Following employment of suction applied to a duodenal tube passed into the stomach, the dyspnea and cyanosis decreased and the abdomen softened. The stomach, however, could not be emptied completely, as indicated by subsequent films. The improvement attending employment of suction, however, was such that the needed operation could now be carried out with equanimity. At operation, the stomach, together with a good portion of the small intestine and colon as well as the spleen were found to have herniated through an hiatus in the left diaphragm. Employing a suggestion of Dr. C. H. Mayo (*Annals of Surgery,* 86:481, 1927), a catheter was introduced through the aperture into the left thorax; air was injected gently with a syringe and it was startling to observe how the small bowel and other viscera which could not be delivered by pulling, came back gradually into the abdomen spontaneously with the establishment of atmospheric pressure in the thorax. The edges of the diaphragmatic aperture were smooth and its location was typical for a congenital pleuro-peritoneal hiatus hernia. Dr. Weinberg, of Omaha, had told me of an excellent plan in the repair of such defects which he has since published (*Surgery,* 3:78, 1938), a plan which I found very helpful in closing the defect. After the placement of interrupted silk sutures, the peri-renal fascia—a very extensive sheet of strong tissue—was sutured over the site of repair. The patient has remained well. This suggestion of Weinberg should prove very helpful in the repair of large diaphragmatic defects.

In pleuro-peritoneal hernias of the right diaphragm, it is the liver which enters the thorax. The other intraperitoneal viscera can not enter the thorax because of the engagement of the liver in the diaphragmatic aperture.

I have had one operative experience with pleuro-peritoneal hiatus hernia in the newborn. Dr. Mayo's maneuver for the reduction of the herniated viscera was then not known to me. After return of the viscera to the peritoneal cavity and closure of the diaphragmatic defect, I found that I could not close the abdominal incision. The peritoneal cavity was too small to hold the returned viscera. I had to content myself with suture of the skin. At postmortem examination, the left kidney was still in the thorax.

Dr. F. C. Rodda, Minneapolis: The diagnosis of congenital diaphragmatic hernia may present some difficulties. My own experience concerns two cases. In one child, diagnosis was made and the child operated upon, with excellent results. The other case was that of an infant four weeks of age with the prevailing symptoms of vomiting, cyanosis and collapse. The same roentgenologist who had confirmed our diagnosis in the first case made a similar diagnosis in this child. At operation, we found an enormously dilated stomach and much of the bowel in the left chest. The lung was collapsed and the diaphragm, which presented a very thin poorly-developed musculature, was crowded up to the apex, and, to our chagrin, we found a well-developed pyloric stenosis. Whether the findings were due to an injury of the phrenic nerve or a lack of development of the muscles of the diaphragm, we were unable to determine. There was no opening in the diaphragm and consequently no hernia; but the physical signs and x-ray findings were very similar to those found in a true hernia. The child died.

Dr. Kenneth Bulkley, Minneapolis: The discussion of diaphragmatic hernia is always instructive because none of us has seen many such cases. Little has

been said here tonight regarding traumatic diaphragmatic hernia and for this reason I would like to report a diaphragmatic hernia, the result of a stab wound. This involves the case of a boy about ten years of age who was brought into Bellevue Hospital, New York, a good many years ago, just as I was making rounds. The history was that this boy immediately previously had been stabbed with a banana knife while attempting to steal bananas. The wound of entry lay in the left posterior chest, was about one inch in length, and through it protruded a tongue of fat which manifestly was omentum. At this time the boy had no abdominal symptoms whatsoever. The chest was opened through an intercostal incision, using a Lillienthal retractor, the omentum was pulled still further from the abdomen, amputated and reduced within the abdominal cavity, and a slit in the diaphragm about one inch in length was repaired without undue difficulty. The chest was closed without drainage; the pneumothorax cared for by aspiration, and the patient returned to his bed.

This case illustrates the necessity of bearing in mind the possibility of an intra-abdominal injury in cases of traumatic diaphragmatic hernia, particularly by stab wounds or gunshot wounds, inasmuch as on the following morning this boy showed very definite signs of an intra-abdominal hemorrhage of an extent sufficient to necessitate intervention. Following transfusion, the boy's abdomen was opened and there was found an exceptionally long cut of his spleen, bleeding profusely. This could be controlled only by a splenectomy, which was done. The boy went on to ultimate recovery.

Dr. Jones, in closing: I wish to thank the members for their discussions. I have nothing particular to add, but wish to leave the thought that we should always bear in mind the possibility of the presence of a diaphragmatic hernia when making diagnoses referable to the chest and upper abdomen. It is not uncommon for an exhaustive examination to reveal nothing except a small diaphragmatic hernia. If circumstances permit the repair of the hernia, the patient is frequently cured.

The meeting adjourned.

Albert G. Schulze, M.D., *Secretary.*

Meeting of February 9, 1938

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, February 9, 1938. Dinner was served at 7 o'clock and the meeting was called to order at 8:15 o'clock by the president, Dr. R. T. LaVake.

There were forty-nine members and one guest present.

Minutes of the December and January meetings were read and approved as read.

Upon ballot the following men were elected as candidates for active membership in the Academy:

Dr. Lee W. Barry.....St. Paul
Dr. Roy E. Swanson.....Minneapolis

CLINICAL TETANUS: A SURVEY.

Report of Cases With Unusual Early Symptoms

E. A. Regnier, M.D.
Minneapolis

Dr. Regnier read his inaugural thesis on the above subject.

Abstract

Twenty-nine clinical cases of tetanus are reviewed. Tetanus toxins are disseminated through the blood stream and not through motor nerve trunks as heretofore believed.

Trismus may be a late symptom of tetanus. Any regional muscle group may be primarily involved. Two cases are reported in which initial symptoms were all referable to the abdomen and simulated an acute abdominal catastrophe. A third case is reported in which the masseters were the last group of muscles to be affected.

A history of abdominal cramp followed by profuse perspiration, board-like rigidity and spasm of abdominal muscles, other findings of peritonitis being absent, should lead one to suspect tetanus.

Discussion

Dr. Carl B. Drake, Saint Paul: There are some distinct disadvantages to the present prophylactic treatment of tetanus. There is a certain group of individuals who have a natural or acquired sensitivity to horse serum. There is a much larger group of individuals who, on account of their occupation, are very subject to injury in which infection to tetanus is quite likely. Considerable work has been done by some French investigators in developing an alum-precipitated tetanus toxoid. This toxoid contains no horse serum and two or three injections of 1 c.c. are given at two to three month intervals. In case of a suspicious injury an additional injection is given which raises the antitoxin in the blood sufficiently in most cases. I have not encountered any report of extensive use of the toxoid, which of course is necessary before its clinical value can be determined. It has been used sufficiently, however, to warrant its acceptance by the Council on Pharmacy and Chemistry.

Dr. C. B. Wright, Minneapolis: Are there any late sequelæ of tetanus such as neuritis or late cerebral symptoms? In looking through the literature I could not find any.

Dr. J. A. Johnson, Minneapolis: I appreciate very much Dr. Regnier's thorough discussion of this subject, especially his description of the onset of muscular spasm in the abdomen, which is so apt to be mistaken for some intra-abdominal lesion.

My first introduction to tetanus was when I was ten years of age. One of my playmates received a firecracker injury on the 4th of July and died as a result of it. I still remember his terrible suffering.

It has been my misfortune during many years to see a large number of these cases. Over twenty years ago when I was house surgeon in a large hospital in Chicago, it was then our practice that all injury cases receive a prophylactic dose of antitetanic serum while still in the emergency room. During a period of five years I did not see a single case of tetanus develop in any of these cases. We saw, however, many cases that came to the hospital that had not had the pro-

phylactic serum. This serum has been so well established as a preventative of tetanus that it must now be considered a criminal neglect not to administer it in cases that can be suspected of having been infected with tetanus.

At that time also we had considerable difficulty with some cases of post-operative tetanus developing in clean wounds. That was due to catgut. So much has been done in the sterilization of catgut that this condition is not now feared as it used to be. Years ago, after a case of tetanus had developed into advanced stages, the patient practically never recovered. As time has gone on, it has been my experience that more and more of these late cases have been cured; perhaps because now we are giving them larger doses, and I also believe the serum is more potent than it used to be. I believe avertin is one of the best methods of controlling the spasms, especially when they are continued and very severe.

Dr. W. E. Camp, Minneapolis: I would like to ask Dr. Regnier if he has any statistics on the number of cases that develop after head injury as compared to the number developing after injury to the extremities?

Dr. Regnier, in closing: In answer to Dr. Drake's remark about giving prophylactic serum, I wish to state that there has been developed a toxoid for prophylaxis of tetanus. There are very favorable reports, especially in foreign literature, about the use of alum-precipitated tetanus toxoid. This toxoid has been universally adopted in the French Army in the last few years. Some of our American biological houses now have tetanus toxoid on the market. There is no doubt but what there is danger in giving serum to an allergic individual, but these people can be desensitized. Unquestionably the use of toxoids would obviate this danger of serum reaction. Reports from the French Army, members of which have been using toxoid for a considerable length of time, state that once an individual has obtained immunity and is subsequently wounded, he is then given subsequent protective doses of toxoid.

My answer to Dr. Wright's question is that there are no permanent sequelæ of tetanus. Pathologically there are no typical lesions in fatal cases. These patients, when they survive the disease, become greatly emaciated and their muscles lose their tone and become exceedingly flabby, but there are no permanent structural changes.

Dr. Johnson stresses the use of prophylactic serum. I can think of no legitimate excuse for not using prophylactic serum in all puncture wounds, wounds harboring foreign bodies and wounds harboring secondary pyogenic organisms. As regards the amount, 1,500 units is considered standard but this dose must be repeated two or three times at weekly intervals in cases that have a great deal of suppuration and where the infections are prolonged. It is a well known fact that one prophylactic dose will not always be protective. One of our cases received prophylactic serum thirteen days after he was wounded and within forty-eight hours of the time tetanus developed. This case promptly died. Another case received prophylactic serum seven days after his injury and subsequently developed tetanus and survived the infection.

In reply to Dr. Camp's question about tetanus associated with head injuries, I am frank to state that there were only two cases in this series that might have had scalp wounds as the focus of infection. One of these cases had a hand injury, therefore the source of infection was not definitely determined. One other case had a neck wound and the incubation period in this case was only four days and terminated fatally. Infections following head injuries are rather infrequent but when they do occur are often very severe. It is surprising, from a review of the literature, how few head injuries are complicated by tetanus infection.

I am very grateful to these gentlemen for their discussions.

RETROPERITONEAL DERMOID WITHIN THE PELVIS

Martin Nordland, M.D.
Minneapolis

This case is that of a patient who had an extraperitoneal tumor within the pelvis. It is of interest because of the difficulty experienced in its removal and because of complications caused by its presence during obstetrical delivery about five months previously.

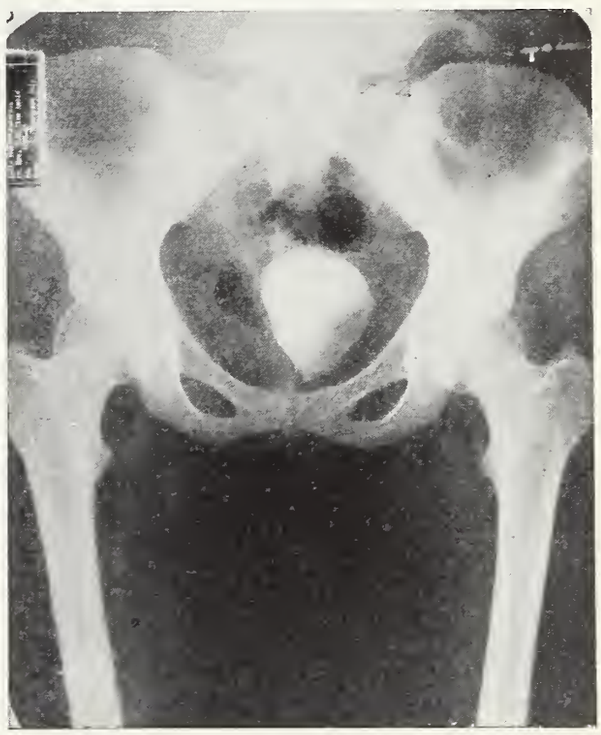

Fig. 1. Cyst anterior to the lower portion of the sacrum and coccyx.

The history of this case reveals that on September 2, 1937, the patient was brought into the hospital by her attending physician for the induction of labor because she was two weeks beyond the date of expected delivery. She had gained 65 pounds during pregnancy and seven pounds in the last week. Medication and bag induction failed to induce labor but a second attempt with castor oil and quinine caused the onset of pain on September 8, at about noon. Pains began slowly and continued with increasing severity without much progress all through the day of September 9. An obstetrical consultant was then called in by the attending physician, who had noted the presence of "a tumor in the vagina." Rectal examination had given this information. The consultant in his examination described the tumor as "antero-rectal." He stated that the tumor was tense and firm, contained fluid and was not tender and further that it extended in the direction of the left sacro-iliac joint. With the pains, the lower margin of the tumor extended down to about 1½ inches above the anal ring. The cervix was completely dilated above the protruding margin of the tumor.

They felt that aspiration was advisable and, with the

finger in the rectum, they inserted a large needle up to the left side of the rectum and punctured the tumor mass. Nothing was aspirated, but when they withdrew the needle it was filled with sebaceous looking material. A second attempt with a larger needle was also unsuccessful. The skin was then incised and a blunt scissors was directed upward in the same line and in this manner the tumor was widely opened. About one pint of heavy, cheesy, sebaceous material without odor was evacuated. The patient delivered about three hours later without difficulty.

They noted with interest that with each pain a long ribbon of the sebaceous material about 3 inches thick and 10 inches long would be evacuated. Most of the material was saved and by the time the baby's head was on the pelvic floor more than a liter of the material had been collected. Laboratory examination of the material showed it to contain much squamous epithelial and cholesterin substance. The patient promptly became infected and ran a temperature, the drainage became thinner and developed much offensive odor. It was necessary to reestablish drainage through the insertion of catheters into the cystic cavity on the ninth day. These catheters were inserted for a distance of about 10 inches, and as a result of the procedure the temperature dropped promptly. When the catheters were removed five days later, the temperature again became elevated and, with reinsertion and establishment of drainage, the temperature again receded. The patient left the hospital at the end of six weeks.

I was called to see the patient just before she was dismissed. She was still having recurrent elevations of temperature. Examination of the uterus revealed the fundus retroverted and pressed over to the right with the cervix behind the symphysis pubis. There were two fistulous openings high in the perineum near the lower left side of the vaginal outlet. Because her general condition was poor and because it was only five weeks since the delivery of her baby, it was thought best to postpone the surgical removal of the pelvic tumor for several weeks.

By the first of January, 1938, the patient returned to the hospital in very good condition. The two fistulous openings were still present and the patient stated that there had been varying amounts of discharge since she left the hospital in November.

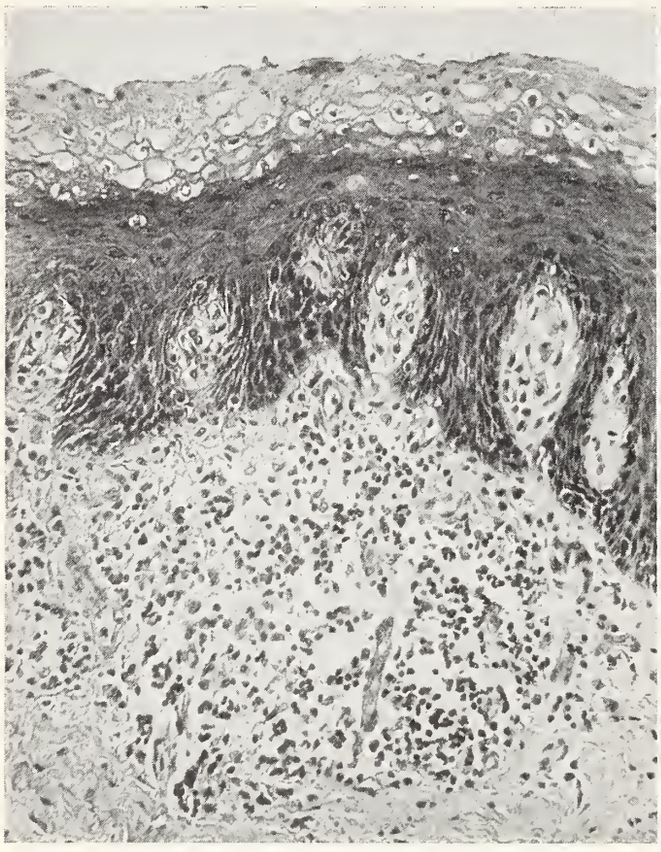

Fig. 2. Microscopic section of cyst wall showing characteristic lining with stratified squamous epithelium and chronic inflammation underneath.

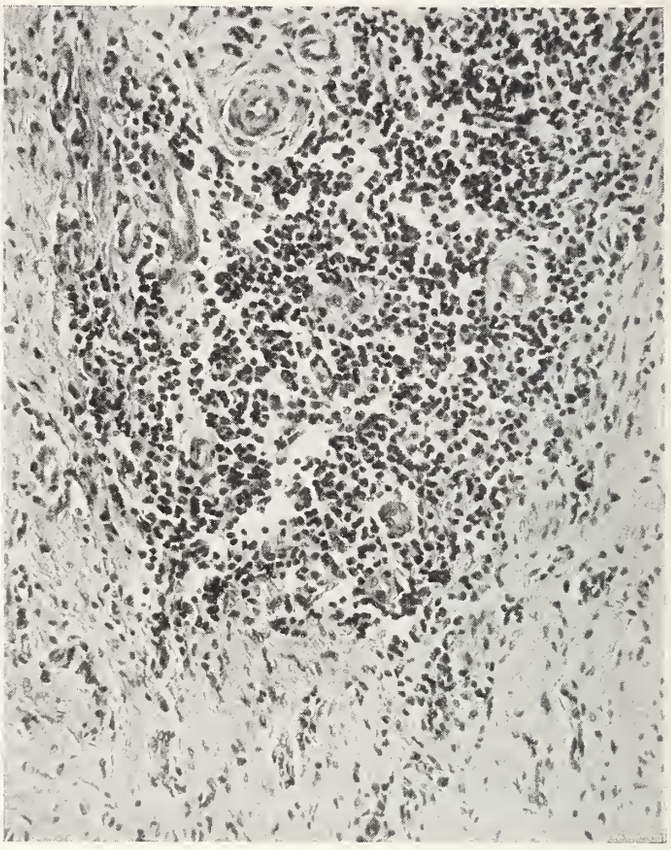

Fig. 3. Microscopic section of cyst wall showing round cell infiltration, plasma cells and pus.

Stereoscopic antero-posterior and lateral plates were made of the pelvis after the injection of the sinus tract with an opaque material. The tract was demonstrated from the region of the labia to a position anterior to the lower portion of the sacrum and coccyx, where there was a fairly large cyst (Fig. 1).

On January 12, 1938, the patient was taken to the operating room. Under general anesthesia a double elliptical incision 3 inches in length was made to the left of the vagina extending down to the perineum including both the fistulous openings. A No. 20 catheter was pushed up into the lower fistulous opening for a distance of about 12 inches. The contents were held in the sac by clamping the catheter. The fistulous tract was dissected out using the catheter as a guide and the lower end of the sac was exposed, dissected free from the ramus of the pubis and the hollow of the sacrum. With the assistant's finger in the rectum, it was possible to free the fistulous tract from the rectum without injury to that wall. The left vaginal wall was similarly protected by keeping a finger in the vagina during the dissection. Because it was impossible to get the highest portion of the sac from below, it was thought best to finish the operation through the abdomen. Two large cigarette drains were placed into the wound from below, and the abdomen was opened in the midline below the umbilicus, the peritoneum over the left broad ligament split vertically so that the field of operation which was begun from below was exposed through this opening.

The remaining portion of the sac was dissected through this approach and a 3 inch pack was placed in the cavity so created. This was tied to one of the cigarette drains introduced from below. The opening in the broad ligament was sutured and the abdomen closed. The mass removed with the fistulous tract was the size of a large fist. It was found in the pelvis between the vault of the vagina and in front and lateral to the rectum. It was fastened to the ramus of the left pubis anteriorly and to the periosteum of the sacrum near the left sacro-iliac joint. During the abdominal procedure, the left ureter and the femoral vessels were exposed. The sac contained sebaceous and suppurative material and had a smooth lining.

The laboratory submitted the following report:

"Microscopic sections show walls of cyst containing fibrous tissue some of which is elastic. It has a lining, round cells, plasma cells and pus. Some points covered with stratified squamous epithelium with considerable chronic inflammation underneath" (Fig. 2 and Fig. 3).

Pathologically, dermoids are of interest even though they are quite commonly encountered by the surgeon of average experience. Dr. E. T. Bell has suggested that this tumor might be classified as an epidermoid. Bowles states that cystic teratoma must be distinguished from other dermoid tumors which are congenital sequestration tumors found at the lines of embryonic fusion and which arise by the development and inclusion of cells of ectodermal origin. It is possible for retroperitoneal teratomas to develop from the isolated blastomeres or germ cells of an accessory retroperitoneal ovary. It is possible that this is what happened in this case. An ovarian dermoid is considered large when it reaches the size of a grapefruit. Most dermoids range from the size of a hen's egg to an orange. As noted in the history above, this cyst contained more than a quart of sebaceous material at the time of delivery and was as large as a good sized fist at the time of the operation. Koucky, in a recent analysis of a hundred cases of dermoids, states that a typical ovarian dermoid, cleansed of its fat and loose hair, reveals a projection into its cavity. This projection known as the plug, pseudomamma, or focus is covered with hairy skin and contains the parenchyma of the tumor. The rest of the cyst wall is smooth and glistening, reddish in color and wrinkled and 1 to 2 mm. in thickness. The plug or focus is the essential part of the dermoid. Its growth and secretory activity determines the size of the tumor. Forty-one per cent of Koucky's cases had a smooth interior and revealed only slight thickening of the lining to mark the site of the plug and focus. No focus was demonstrated in this case. In his conclusion, Koucky states that dermoids usually occur in the 4th and 5th decades, seldom interfere with child-bearing and that the symptoms are usually due to pressure on the surrounding organs. Our patient was twenty-three years old, and the tumor was recognized because it did interfere with the delivery of the child. Roentgen examination before delivery gave no information. The patient made an uneventful recovery following the removal of the cyst and is in good condition at the present time.

The meeting adjourned.

Albert G. Schulze, M.D., *Secretary.*

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

J. P. MURPHY—STORMY PETREL OF SURGERY. Loyal Davis. New York: G. P. Putnam's Sons, 1938. Price $3.00.

No American surgeon ever received more criticism at the hands of his fellow surgeons than did J. B. Murphy of Chicago. Few received more honors at the hands of the profession and public. This biography is beautifully written by a Chicago surgeon who knew J. B. and is as impartial as a biography could be. After reading the volume one can appreciate how this surgeon's dynamic personality, his inconceivable industry and his unsuppressable ambition led him to the top of the ladder but not without his being the target for much mud slinging and some justifiable criticism. This biography reads like a novel and will prove interesting especially to one who ever had the privilege of attending one of J. B.'s clinics. C. B. D.

HEART FAILURE. Arthur M. Fishberg. 788 pages. Illus. Philadelphia: Lea and Febiger, 1937.

Of the many volumes concerning heart disease which have appeared in recent years none has been of more value to the physician than the publication under review. The author has well succeeded in bringing together the vast amount of work which has been done in recent years on problems concerning the circulation, and he has pointed out the reasonable deductions

which can be drawn from this work. The work is essentially one on pathologic physiology of the circulation, a valuable contribution to our knowledge of the reasons for the various manifestations of circulatory disease.

The author's descriptions of and differentiations between cardiac failure and peripheral circulatory failure lead to an intelligent appreciation of the care of these conditions. They have been all too often regarded as simply heart failure.

The work may be divided into three major sections. The first describes the signs and symptoms which accompany heart disease, as well as the fundamental circulatory change which can be measured in quantitative terms. The methods of production of these changes are described. The second deals with the application of these fundamentals to the various types of circulatory failure, and the third part discusses the treatment which modern concepts indicate.

Any adverse criticism would be too insignificant to mention in discussing a work which has so much to offer the physician as does this volume.

JOSEPH F. BORG, M.D.

POISONING WITH CICUTA MACULATA OR WATER HEMLOCK

(Continued from Page 262)

in abundance. While one had eaten the roots, the other had partaken only of the flowers. It is interesting to note that the one who had eaten the root and stock was very sick and had convulsions, while the other who had eaten the flowers but no roots had no convulsions.

In the older boy, besides the violent convulsions, there was unconsciousness, protruding eyeballs, and frothing at the mouth. The froth was blood tinged. Cyanosis was extreme and the corneal reflexes absent. The jaws were set and there were severe twitchings of the muscles of the face. The abdomen was negative. The fingernails were cyanotic and the hands were tightly clinched.

During the convulsion it seemed as if the boy was about to die from suffocation. The convulsions lasted on the average of about ten minutes, being followed by a state of exhaustion. The patient remained cyanotic and unconscious. This patient had five convulsions. Following the last convulsion, the boy, exhausted, fell into a deep sleep.

The younger boy, who had eaten the blosssoms, complained of general weakness, faintness and nausea. Slight cyanosis and nervous twitchings were also present. Dizziness was a prominent symptom. There was evidence of general collapse and the extremities were cold.

Treatment consisted of gastric lavage and enemas. In the other boy, it was necessary to use a metal mouth gag in order to pass the stomach tube. After his stomach was evacuated, it was necessary to administer morphine hypodermically. Stimulants such as strychnine, black coffee, strong tea, whisky, caffeine and sodium-benzoate were administered. Artificial respiration was necessary. His urine showed a trace of albumin the first day. The second and third day the urine was increased in amount but it contained an abundance of blood and albumin. His condition remained the same until the seventh day when he appeared more rational and his appetite began to improve. There were still dark rings under his eyes. The urine had increased in amount and contained less blood and albumin. The kidney condition in general was treated by rest in bed, elimination, low protein and a salt-free diet. Iron, manganese and copper were given later to combat the anemia. Recovery followed.

The younger boy, who could swallow was given hot water containing tameric acid at thirty-minute intervals followed by lavage. This was followed by prompt recovery.

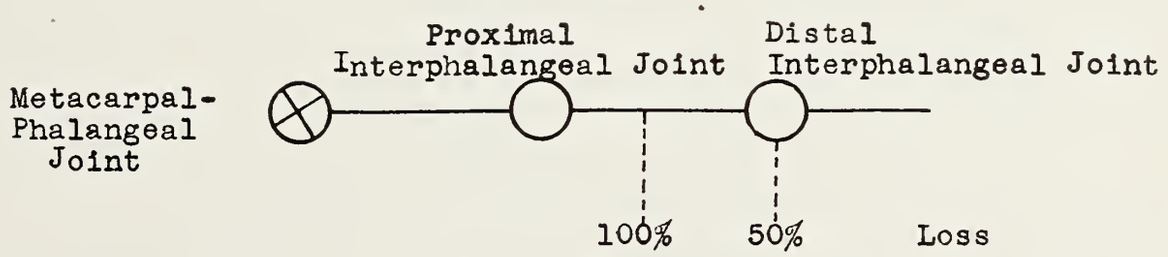
ESTIMATION OF PERMANENT DISABILITY

GEORGE R. DUNN, M.D.
Minneapolis, Minnesota

THE Industrial Commission of Minnesota ultimately determines the amount of disability in a compensation case.

Members of the medical profession usually furnish an opinion or several opinions, as the case may be. This opinion is called an estimate of disability. The estimate of disability should be based on the permanent loss of general usefulness of the extremity or portion of the extremity involved. Occupation is not considered in making the estimate.

The estimate of permanent disability is expressed by the medical man as a certain percentage of loss of function of the extremity or portion of the extremity involved. For example:



10% loss of function of the right arm.
10% loss of function of the right hand and wrist.
10% loss of function of the right hand.
10% loss of function of the right thumb, index, middle, ring, or small finger, as the case may be.

Leg	200 weeks	
Foot and ankle	150 weeks	
Foot	125 weeks	
Great toe	30 weeks	
Second toe	10 weeks	
Third toe	10 weeks	70 weeks
Fourth toe	10 weeks	
Fifth toe	10 weeks	

A knowledge of these values is necessary for the medical man in furnishing an estimate of disability. For example, in a case involving the complete loss of the thumb with additional injury to the palm of the hand, the estimate would be based on a percentage of loss of function of the hand but would exceed a 40 per cent loss of function of the hand for the thumb alone (value 60 weeks) constitutes 40 per cent of the hand (value 150 weeks).

Certain losses by amputation are definitely fixed by law.

FINGER AMPUTATIONS

Amputation of distal phalanx 50 per cent and amputation of distal and half or more of middle phalanx 100 per cent of the finger.

Certain values in weeks have been fixed by law for extremities and component parts.

Arm	200 weeks	
Hand and wrist	175 weeks	
Hand	150 weeks	
Thumb	60 weeks	
Index finger	35 weeks	
Middle finger	30 weeks	160 weeks
Ring finger	20 weeks	
Small finger	15 weeks	

In case the terminal phalanx of a finger has been amputated (50 per cent of finger), and in addition there is limitation of movement at the proximal interphalangeal joint, due allowance must be made for the additional disability, i.e., 50 per cent (loss by amputation) plus additional disability due to the limitation of movement at the proximal joint.

If an amputation has been done below the

knee, leaving a satisfactory stump for a useful artificial limb, the disability constitutes the loss of a foot and ankle. Various other amputations of arms and legs as well as loss of hearing, loss of an eye, disfigurement, and certain combinations of these conditions are covered by law. Permanent partial disability and permanent total disability are also legally defined.†

However, in a large number of cases medical men must form an opinion of the percentage of disability by contrasting the injured member with the normal and, while no absolute rules or values can be set forth, certain principles may perhaps prove helpful, subject to proper correction.

In estimating disability of the arm, four important considerations are:

1. Range of movement.
2. Strength and stability
3. Pain.
4. Tactile sensation.

In estimating disability of the leg, five important considerations are:

1. Range of movement.
2. Strength and stability.
3. Pain.
4. Shortening.
5. Tactile sensation.

In evaluating pain, one is guided by complaints, muscle reaction, limitation of motion of joints, measured atrophy of the muscle and organic findings such as roughened joint surfaces, nerve lesions and other conditions. A fracture of the os calcis may cause little deformity of the foot but if the subastragaloid joint is rough and painful, there may be a considerable loss of function.

Tactile sensation can be fairly definitely tested and, especially in the hand, may cause a definite impairment of function.

Strength and stability of the various portions of the extremities are closely related and are of particular importance in the lower extremity. It must be remembered that full strength returns only with active prolonged use of an injured extremity. The injured member may be compared with the uninjured and the strength of the hands tested by a grip machine and fairly accurately measured.

Important nerve lesions may cause, through muscular paralysis, loss of range of movement and loss of strength; and by the sensory nerve lesion, loss or impairment of sensation or pain.

Shortening, especially of the lower extremity, is of importance. The disability caused by shortening of the lower extremity, depending on the symptoms produced, frequently falls within this range:

Shortening of 1 inch..... 0-10% of leg
Shortening of 1–2 inches.....10-20% of leg
Shortening of 2–3 inches.....20-40% of leg

Range of movement, strength and stability usually reflect fairly well the disability present, for if movement is painful, the usual result is limitation of movement and diminished strength. Strength, as we have seen, can be fairly accurately determined by the grip machine or by actually comparing the strength of the injured and uninjured extremities in various movements against the resistance of the examiner's hands.

It consequently follows that in a large number of cases the estimate of disability is closely related to the loss of the normal range of movement. Certain portions of the normal range in certain joints, particularly the shoulder, are, undoubtedly, of greater value and more generally useful than other portions. This is a matter upon which any particular individual can but express an opinion and only roughly approximate.

To proceed in orderly manner, it would first seem desirable to valuate the various normal joints with regard to the extremity as a whole. Having fixed a value on the normal joint and knowing the normal range of movement of this joint, it should be possible to fairly accurately estimate the percentage of disability to the extremity occasioned by a certain loss of the normal range of movement at this particular joint.

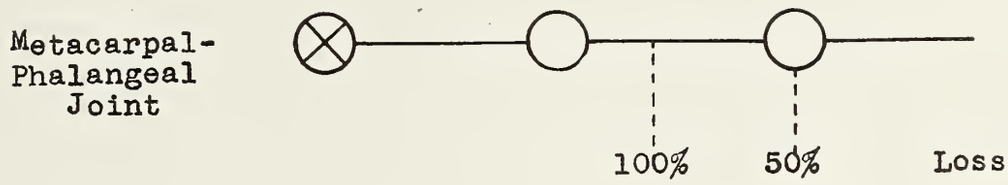
Finger

Let us first consider the finger. As determined by our Minnesota Law, the amputation of the distal phalanx constitutes a 50 per cent loss of function of the finger and a phalanx and a half or more constitutes 100 per cent loss.

If a finger amputated at the distal interphalangeal joint constitutes a 50 per cent loss of the finger, then ankylosis of this joint alone would seem to furnish a slightly more useful finger or perhaps a 40 per cent loss of function of the finger. Obviously the loss of movement of the two interphalangeal joints (proximal and

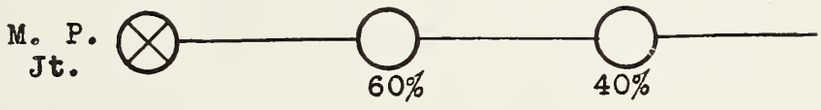
†See Labor Laws of Minnesota.

distal) constitutes 100 per cent loss of the finger; therefore ankylosis of the proximal interphalangeal joint may be said to constitute 60 per cent of the finger.



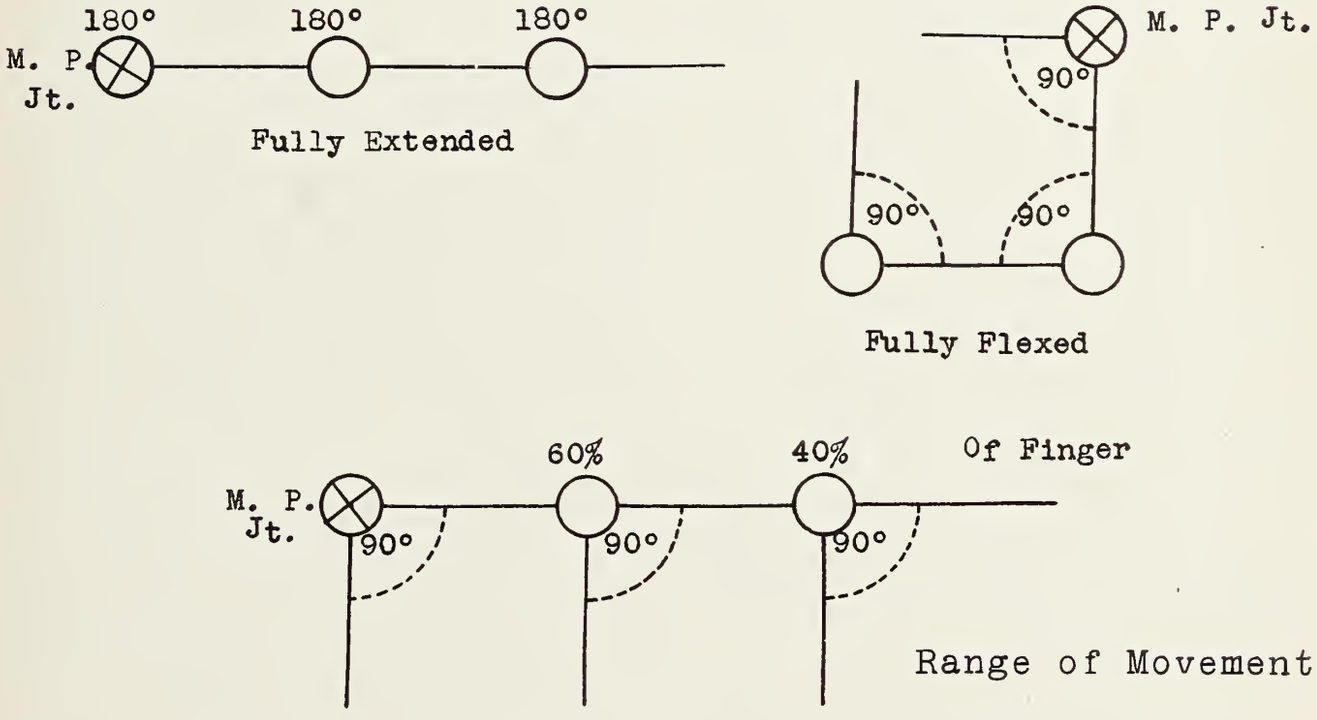
Roughly, the middle finger can be flexed at the various joints from a straight line (180°) through 90° (to a right angle), each joint having a range of approximately 90°.

Having fixed the per cent of value of the normal joint with respect to the finger and the normal range of movement of this joint, one may then compute the percentage of loss to the finger of any certain number of degrees of loss of movement at this joint.



DISTAL JOINT (40 PER CENT OF FINGER)
(RANGE 90°)

Roughly 10° loss of movement = 5% (loss of function of finger)
Roughly 30° loss of movement = 15% (loss of function of finger)
Exactly 45° loss of movement = 20% (loss of function of finger)



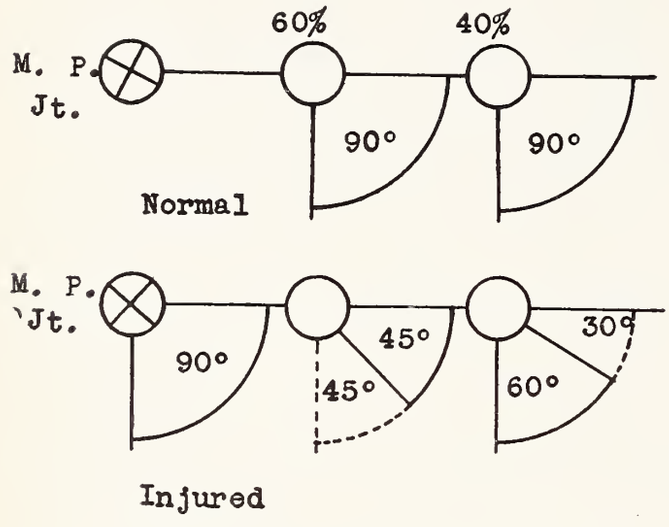
LOSS BY AMPUTATION (FINGER)

PERCENTAGE VALUE OF JOINTS OF FINGER

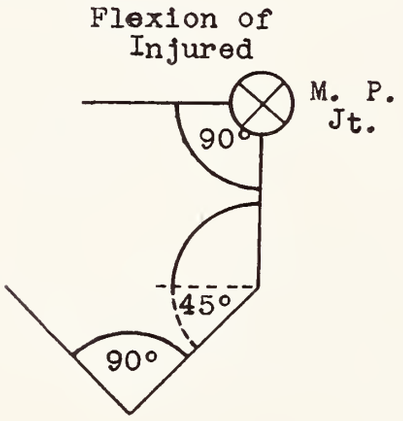
RANGE OF MOVEMENT OF JOINTS

PROXIMAL JOINT (60 PER CENT OF FINGER)
(RANGE 90°)

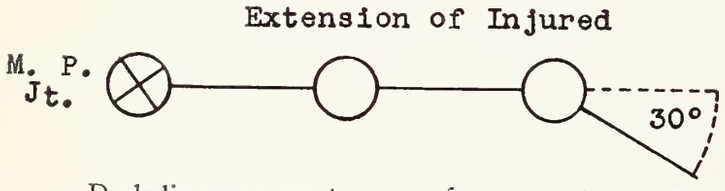
Exactly 30° loss of movement = 20% (loss of function of finger)
60° loss of movement = 40% (loss of function of finger)
90° loss of movement = 60% (loss of function of finger)



If there is some loss of movement at both joints, compute the percentage loss to the finger



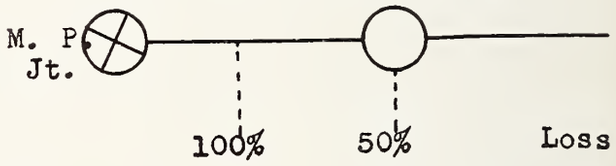
UNIVERSITY OF MARYLAND
LIBRARY
SCHOOL OF MEDICINE



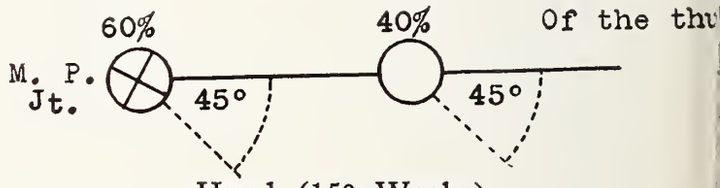
at each joint and add the two to determine the total.

Loss of extension constitutes just as definite a loss of motion as loss of flexion and can be computed in the same manner.

Let us take a concrete example of disability to a finger which has a 30° loss of extension in the distal joint and a 45° loss of flexion in the proximal joint.



Dark lines represent range of movement at metacarpal phalangeal, proximal and distal interphalangeal joints, respectively. Dotted lines represent loss of normal range of movement.



Thumb (60 Weeks)

The first metacarpal is relatively quite movable and in estimating disability to the thumb the metacarpal phalangeal joint may be valued at 60 per cent of the thumb and the interphalangeal joint at 40 per cent of the thumb. Comparison of range of movement should always be made between the normal and injured thumb as there is considerable variation in individuals but the average is probably 45° at the metacarpal phalangeal joint and 45° at the interphalangeal joint when the tip of the thumb is approximated to the palm of the hand at the base of the small finger.

LOSS BY AMPUTATION (THUMB)

NORMAL RANGE AND VALUATION OF JOINTS OF THUMB

Hand (150 Weeks)

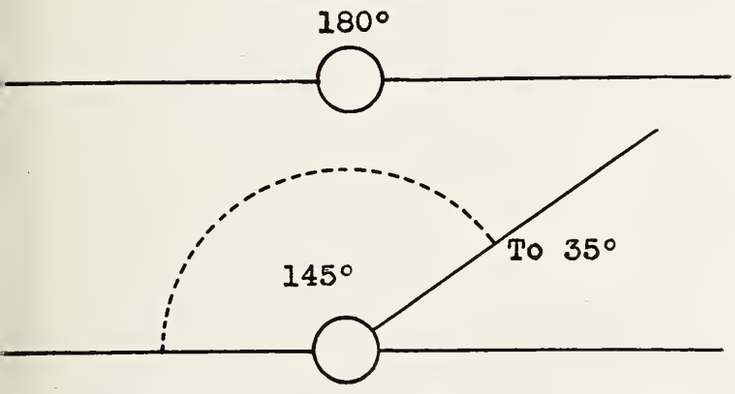
In estimating disability of the hand, the function of the fingers is taken into consideration and, in addition to this, any disability to the palm or dorsum of the hand.

Wrist (Estimate Based on Hand and Wrist, 175 Weeks)

Complete ankylosis of the wrist in good position (30° dorsiflexion) probably constitutes approximately 30 per cent loss of the hand and wrist. One must consider that movement of the wrist, when lost, prevents the individual

	Metacarpal Phalangeal	Proximal	Distal Joints
Value of Joint (% of finger)		60%	40%
Normal Range	90°	90°	90°
Range of Injured Finger	90°	45°	60°
Loss of Range	0°	45°	30°
Loss (exactly) at Proximal Joint	45°/90°	or ½ of 60% equals	30%
Loss (roughly) at Distal Joint	30°/90°	or ⅓ of 40% equals	15%*
Total Percentage Loss of Finger			45%

*Take closest 5 per cent.



making normal use of the hand by interfering with getting the hand into proper position. Any actual injury to the hand constitutes an additional disability. Wrist joint movements vary considerably but usually the normal and abnormal joint movements can be compared and a fairly definite estimate obtained.

WRIST (30 PER CENT OF HAND AND WRIST)

Average normal range as follows (but check with uninjured wrist):

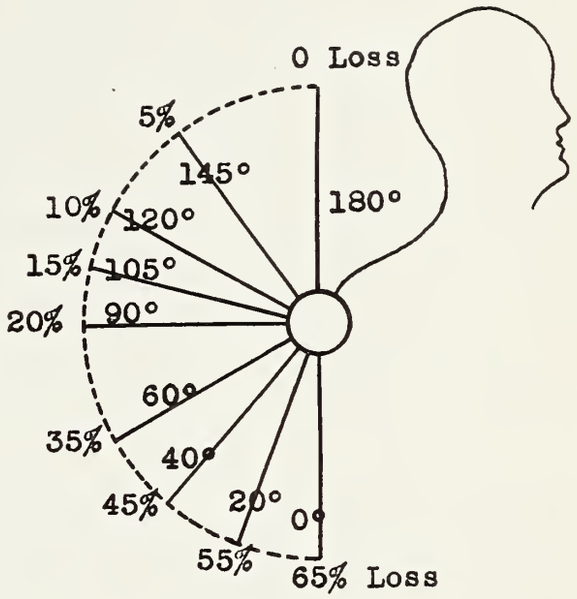
Palmar Flexion	60°	Range 120°
Dorsiflexion	60°	
Radial Deviation	15°	Range 45°
Ulnar Deviation	30°	
Pronation	90°	Range 180°
Supination	90°	

Elbow (50 Per Cent of Arm)
Normal Range 145°

The normal range of the elbow is 145°.

With these figures in mind, one can compute the portion of 50 per cent which a certain amount of the loss of the normal range occasions.

Shoulder (Including Scapular Movement)
(65 Per Cent of Arm)

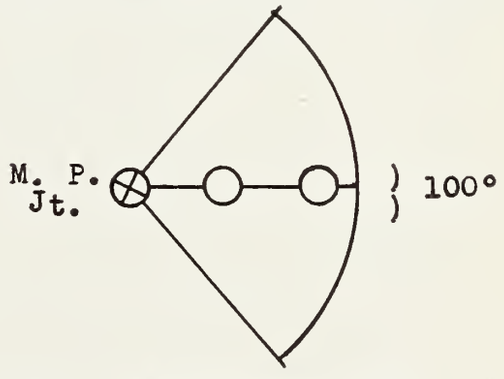


Abduction	180°	
Forward Elevation	180°	
External Rotation	45°	135°*
Internal Rotation	90°	

*Judged by forearm with elbow at a right angle. Not important usually.

Shoulder and scapular movement need not be differentiated for this particular consideration.

External and internal rotation usually do not play a very important part as scapular fixation very rarely occurs.



Movement below the level of the shoulder would seem to be more valuable than movement above this level and value of movement would seem to decrease as the arm travels from the shoulder level to a straight overhead position. In the upper range (145° to 180°) a slight backward or lateral bending of the body compensates and this range is infrequently used. A man 5 feet 6 inches in height with arm extended to 180° attains approximately the level of the hand that a man of 6 feet in height reaches with the hand when the arm is elevated to 145° at the shoulder.

Toes

It is practically impossible to measure accurately individual joint movement in toes; consequently the arc of the tip of the toe describes

TOES (COMPARE WITH NORMAL)

Range (Arc of Tip Approximately 100°)
Loss of 10° equals 10%
Loss of 50° equals 50%

in moving from full flexion to complete extension is a better index. Pain on movement is an important factor in disability of toes as a painful toe may easily be much more troublesome than an amputated toe.

Foot (125 Weeks)

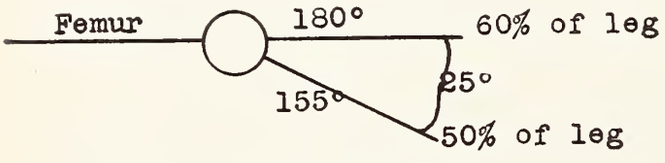
Any injury to the foot involving more than disability to the toes but not affecting the ankle joint, should be estimated on the foot. This in-

cludes the toes, metatarsal and tarsal bones and the subastragaloid joint.

SUBASTRAGALOID JOINT (25 PER CENT OF FOOT)

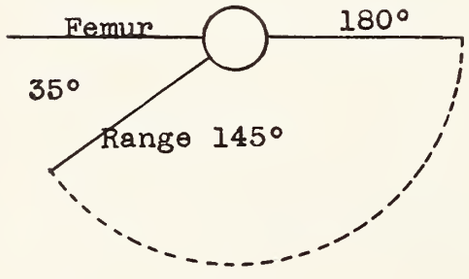
Inversion .....35°
Eversion .....10° } Total 45°

Here again pain is an important factor. A painful subastragaloid joint may create more disability than an ankylosed joint; consequently subastragaloid arthrodesis may be indicated on occasions. Pain and stability are more important factors in the lower extremity than in the arm. On the contrary, loss of movement in the lower extremity is less important than in the arm.



ANKLE (25 PER CENT OF FOOT AND ANKLE)

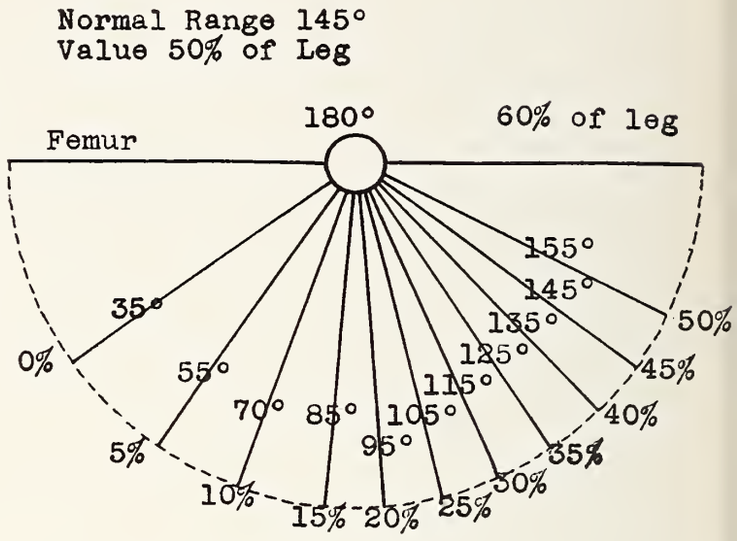
Plantar flexion .....35°
Dorsiflexion .....10° } Range 45°



Knee (50 Per Cent of Leg) (Range 145°)

Ankylosis of the knee in a favorable position, 25° of flexion (155°) probably results in approximately a 50 per cent loss of function of the leg. In an unfavorable position the disability is higher.

ANKYLOSIS OF KNEE



NORMAL RANGE OF KNEE MOVEMENT

The most valuable range of movement of the knee probably lies between 155° and 85°. If the knee can not be flexed to 155°, it renders the leg very awkward. On the other hand, flexion beyond 85° probably becomes less important, relatively.

Stability of the knee is of great importance. An individual who has a good range of movement, but on account of lateral instability of the knee constantly requires a large knee cage, probably has approximately a 35 per cent loss of function of the leg.

Hip Joint (60 Per Cent of Leg)

Abduction .....40°
Adduction .....30° } 70°

Internal Rotation .....30°
External Rotation ....40° } 70°*

*Judged by patella or foot with leg straight or by the leg (below the knee) with hip and knee flexed to a right angle.

Flexion
Extension } 135° (Important)

Abduction, adduction, internal and external rotation are usually not nearly as important as flexion and extension.

A fair degree of precision is desirable in determining these measurements. A grip machine, an instrument for measuring angles, and a tape measure are the only equipment necessary.

In expressing an estimate of permanent disability, one must bear in mind that one is estimating the amount of disability which will actually be permanent, that is, the amount of disability which will eventually be present after medical treatment and reasonable use of the extremity have largely accomplished all improvement possible.

The figures and percentages set forth are not based on any book or article but simply represent one opinion formed and gradually evolved over a period of years* and presented to the medical profession of Minnesota hoping that it may tend to clarify our opinions in this rather intricate matter.

*Somewhat similar but less comprehensive paper, without diagrams, read at noonday session of Hennepin County Medical Society approximately ten years ago.

ENLARGEMENT OF THE HEART*
Its Recognition by the Radiologic Method

PHILLIP HALLOCK, M.D.
Minneapolis, Minnesota

TO determine the presence or absence of enlargement of the heart is obviously of great importance. Cardiac enlargement, if present, generally indicates myocardial disease. Furthermore, the extent of cardiac enlargement is a fair index of the severity of myocardial involvement and in a large measure provides the most satisfactory basis for prognosis.

For the establishment of a diagnosis of cardiac disease, the physician depends chiefly on the symptoms and physical findings. The time-honored symptoms associated with cardiac disease are of inestimable value and will continue to occupy a position of great importance in cardiac diagnosis. On the other hand, certain physical signs have met with reproach in the past and are continuing to be met with increasing disfavor because by their employment the range of precision afforded by such instruments as the electrocardiograph, the sphygomanometer and the x-ray cannot be attained. The value and potentialities of the x-ray in modern cardiology is the subject I wish to discuss.

X-ray or radiologic visualization of the heart is now indispensable in cardiac diagnosis. It offers us an accurate and detailed knowledge of the heart as an anatomic structure, both in its normal and pathologic states, information which extends far beyond the reach and scope of percussion and palpation.

Gross enlargement of the heart can easily be detected in most cases by percussion and palpation. However, slight degrees of enlargement cannot be recognized with certainty by these methods. The difficulties encountered in the use of the percussion method in the obese, the emphysematous and in the female sex are well known. Furthermore, it is a highly subjective method in which the personal equation is far too great. Too often have we been disillusioned by the fantastic ideas that have been and still are held regarding the accuracy that can be obtained by percussion. It can give us only a rough estimate of the transverse diameter of the heart and tells, under favorable conditions, whether there is enlargement in the conus area.

While the percussion method should not be discarded in the routine bedside physical examination, its limitations and the inaccuracies that attend its use should be constantly kept in mind. Sir Thomas Lewis,[8] in speaking of percussion, stated: "It is crucial in measuring to know the error of the method. To have an inaccurate measure may be regrettable, but to have it and not to know it is deplorable."

Because of the lack of faith in the percussion method, recourse has been made to the method of palpation in evaluating cardiac enlargement. This is a valuable bedside technic, but its scope is limited. It offers accurate information about the left ventricle. However, it can be misleading when there is displacement of the heart from any cause or when tachycardia is present.

The Radiologic Method

While the radiologic method for the visualization of the living heart has been employed for many years in Europe, it can be said that its use is still in its infancy in this country, particularly in this region. It is now a universally observed fact that the most experienced cardiologists are skilled in the use of the fluoroscope and many will defer a final opinion until after the radioscopic examination has been completed. What information may one expect to gain by submitting the patient to routine radiological examination? Certainly no organ is so well placed for x-ray visualization as the heart. In the first place, it is almost completely surrounded by transparent lung tissue, and, by rotating the patient, it can be viewed from all aspects. An idea of its volume can be immediately obtained, as well as its position in the chest. In the act of turning the patient, each individual chamber can be identified and scrutinized as to size and shape. The great vessels of the heart as they emerge from their respective chambers and extend beyond their origins can be critically examined. In addition to the visualization of the component parts, the character and extent of

*From the Department of Medicine, University of Minnesota Hospital, Minneapolis. Read before the annual meeting of the Minnesota Heart Society, November 17, 1937.

pulsations of the heart and its pedicle can be recognized and evaluated. Calcification in the pericardium, aortic arch, and heart valves can be actually visualized. Lastly, in cardiac failure,

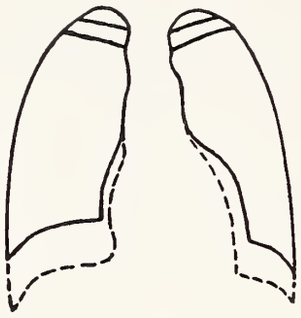


Fig. 1. Outline drawing of normal heart showing effect of changes in height of diaphragm on cardiac silhouette. Continuous line: the end of expiration. Dotted line: the end of deep inspiration. It will be noted that with the lowering of the diaphragm both cardiac borders moved toward the midline. The apparent increase in the size of the heart as a result of a high diaphragm often can give a false impression of cardiac enlargement.

secondary changes that occur in the lung fields and pleural spaces can be recognized.

To disregard this method of examination, Rösler[13] states, means to renounce much of what our best trained sense organ, the eye, can perceive. It has been rightly stated that the radioscopic method provides a means for performing a veritable biopsy of the living heart.[9]

The shape and position of the normal heart as seen by radioscopic examination is variable, depending on a number of factors. Indeed, the chief difficulty in the routine application of radiocardiology is not in the technic, which can be easily mastered, but lies in the interpretation of normal variability and in the recognition of slightly abnormal enlargement. The chief factors upon which alteration in shape and position of the normal heart depend are, for example, age, constitutional build, respiration and position of the diaphragm. It has been demonstrated on anatomical grounds that the contour of the chest cavity determines the form and position of all the organs contained therein. Hence, hearts contained in round chests have a more circular circumference, while those found in flatter chests are more oval in appearance. Individuals of the sthenic type, where the development of the trunk predominates, give the following picture: The mediastinal shadow is short and wide and the diaphragm is high in position. The heart shadow is decreased in height and tends to be boot-shaped—that is, it is tilted upward and to the left. On the other hand, those of the asthenic habitus, in which development of the extremities and vertical dimensions prevail, give a different roentgenological picture. The mediastinal shadow is narrow and long, the diaphragm is low in position and the cardiac silhouette is centrally located, giving the so-called drop heart appearance. The high diaphragm resulting from increased abdominal obesity, meteorism or ascites may cause the heart to assume a transverse position, so that it looks larger than it actually is. Too often a diagnosis of cardiac enlargement is made in these cases, and occasionally healthy men are rejected for life insurance or positions involving physical strain because percussion or palpation suggests that the apex beat is outside the nipple line. The increase in transverse diameter of the heart with advancing age is often not due to an actual increase in heart size, but may be a result of two other factors. The diaphragm is situated higher and an arteriosclerotic and elongated aorta tends to push the heart down on the already elevated diaphragm, thus giving one the impression that there is an increased surface area of the cardiac silhouette. In children the diaphragm is high and the heart appears large in a relatively small chest. One has only to observe the large difference between the position, shape and apparent size of the heart in deep inspiration and expiration to be convinced of the marked variation in shape and apparent size that may occur (Fig. 1).

Parkinson[9] has emphasized the fact that slight scoliosis, particularly in children of school age, may displace the apex beat outward a trifle beyond the nipple line, and, in addition, may result in an exaggerated apex beat, which gives the examiner a false impression of cardiac enlargement. This source of error is present even in radiologic examination. However, by turning the patient slightly to the right, this distortion can be corrected and the cardiac shadow brought back into its normal position.

Cardiometry

Cardiometry, or the quantitative method of determining cardiac enlargement, consists of measuring the distance between certain landmarks on the cardiac silhouette and comparing these measurements with those of normal hearts. For many years investigators have elaborated methods for making cardiac measurements, and have compiled voluminous data upon which to establish normal standards for heart size. After

critically examining the literature, Rösler[13] states that the majority of publications on the subject reveal much evidence of vast waste both of energy and material with resulting confusion and contradictory conclusions. Probably the first method proposed, one which is still in vogue today, is the cardio-thoracic ratio, the relationship of the transverse diameter of the heart to the internal diameter of the chest at its base. In people of normal build, the diameter of the heart should not exceed 50 per cent that of the chest. However, variations are many and this method is too unreliable as a guide as to whether a heart is slightly enlarged.

The investigations of Hodges and Eyster[5] are worthy of note. They have shown that the cardiac transverse diameter could be best correlated with body size, providing height and weight were taken into consideration. As a result, they have developed a formula for predicting the transverse diameter of the heart. Their tables would appear to represent the most scientific attempt from which to estimate the mean physiologic heart size. Authors on the subject of cardiometry agree that the most accurate method to estimate heart size is by determining cardiac volume. Thus, Rohrer[14] attempted to determine heart volume by taking measurements in two planes, and succeeded in obtaining fairly accurate results. These results, confirmed by Kahlstorf,[6] have not yet been routinely introduced into clinical use. A method of determining surface area has been introduced with the hope that the cardiac area will afford a finer index of cardiac size than linear measurements. The difficulty of this method lies in the fact that the upper and lower borders of the heart cannot be sharply demarcated from the vascular shadow above and that of the liver below.

Cardiometry, complicated and bestrewn with imperfections, is, with few exceptions, hardly suitable for routine clinical use. I cannot recall in any instance that the numerical measurements of the heart have afforded me any information not gained by fluoroscopy and inspection of the six-foot film, except where measurements are utilized for comparative purposes in the same individual over a period of time.

Moreover, from an etiologic point of view, it is not so much the total size of the heart that concerns us, but rather the alterations that may occur in its shape. Enlargement of the heart rarely affects all chambers to an equal extent. It has its origin in a certain specified chamber or several chambers, depending on the location of the pathologic process. For example, the strain in hypertension is primarily on the left ventricle, which enlarges in its characteristic manner, in emphysema the strain is on the pulmonary artery and conus of the right ventricle, in mitral stenosis on the left auricle and the right ventricle. Enlargement, with rare exceptions, is therefore regional and in each instance a characteristic pattern of the heart shape is evolved, depending on the seat of the cardiac strain. It can be seen, therefore, why a change in the shape of the heart is of greater importance than the variation in heart size alone. By the recognition of the various patterns of the heart shape, we are thus able to obtain corroborative evidence of the cause of enlargement and to recognize localized changes in early stages. The successful application of the radiologic method in studying cardiac enlargement depends on the recognition of these various pathologic configurations in heart shape. Before this can be attempted, one must be thoroughly acquainted with the normal radiologic anatomy of the heart and great vessels as visualized in the chest from the standard three positions.

Radiologic Anatomy of the Heart

Anatomically the heart is a three-dimensional organ. Radioscopic examination permits study of the heart in three planes; namely, the anteroposterior, the right oblique, and the left oblique positions. In this routine method we inspect the contour of the cardiac chambers from three viewpoints.

In the anteroposterior view (Fig. 2) three borders are visible: the right, left and inferior. The right and left borders of the shadow are easily seen, the inferior border is for the most part lost in the shadow of the diaphragm. The right border beginning superiorly extends downward in an almost straight line for a short distance. This is the shadow of the superior vena cava which at its lower border forms a small notch where it blends into the convex shadow of the right auricle. Just medial to the notch is the origin of the ascending aorta. The right ventricle forms most of the shadow seen anteriorly.

The left border of the heart and great vessels is considerably longer than the right. The most superior shadow is semicircular in contour and constitutes the terminal portion of the aortic arch

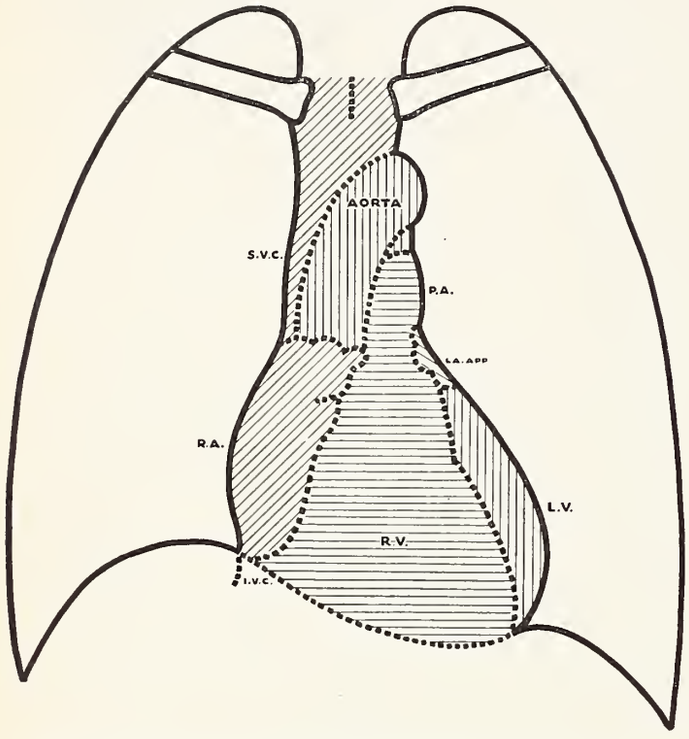

Fig. 2. Outline drawing from teleoradiogram to show normal relationships of cardiac chambers and great vessels in anterior position (after Parkinson and Bedford).

and beginning of the descending aorta. It is often variable in prominence. This shadow is known as the aortic knuckle or knob. Just below this is a flat arch somewhat longer than the aortic shadow. This represents the beginning of the pulmonary artery and uppermost portion of the right ventricle (conus arteriosus). Inferior to this is a small arch, the left border of the left auricular appendage. The remaining and major portion of the silhouette is the left ventricle which forms an elliptical border extending into the left lung field and then turning back toward the midline.

The patient now makes a half turn to the left, bringing the right shoulder to the screen anteriorly so that he is examined through the right chest. This is the right oblique position (Fig. 3). This position affords an excellent view for studying enlargement of the left auricle, pulmonary artery and conus of the right ventricle. The shadow of the left auricle forms the upper two-thirds of the posterior border. Just inferior to this is the shadow of the posterior border of the right auricle. Below this is the cardiohepatic angle in which is the shadow of the inferior vena cava. The latter is made visible when the patient takes a deep breath. Behind the contour of the posterior border of the heart is

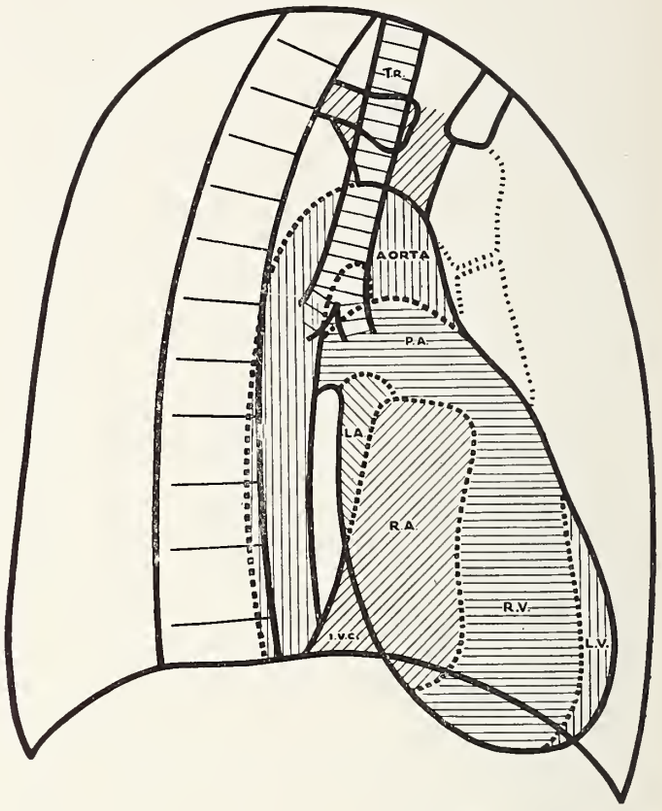

Fig. 3. Outline drawing from teleoradiogram showing normal relationships of cardiac chambers and great vessels in the right (I) oblique position. (After Parkinson and Bedford.)

the clearly illuminated post-mediastinal space. To obtain maximum illumination through this space the patient should be rotated further to the left. (70°). Enlargement of the left auricle partly or completely obliterates the upper part of this space. Massive enlargement of the left ventricle obliterates the lower portion of this area. Anteriorly, if the rotation is only slight, the shadow of the lower portion of the left ventricle participates in the contour. If rotation is greater, the right ventricle becomes border forming. The greater portion of the anterior contour in the right oblique is formed by the conus region of the heart and the pulmonary artery and represents the so-called outflow tract of the right ventricle. This contour, like the one made by the left auricle, represents an important landmark in early pathologic lesions affecting the right side of the heart. Above this appears the shadow of the long aortic arch which sweeps posteriorly and superiorly to disappear in the shadow of the spine. The anterior mediastinal

space, like the posterior one, should always remain clear. The aortic, pulmonary and left auricular impressions of the barium filled esophagus are best studied in the right oblique position.

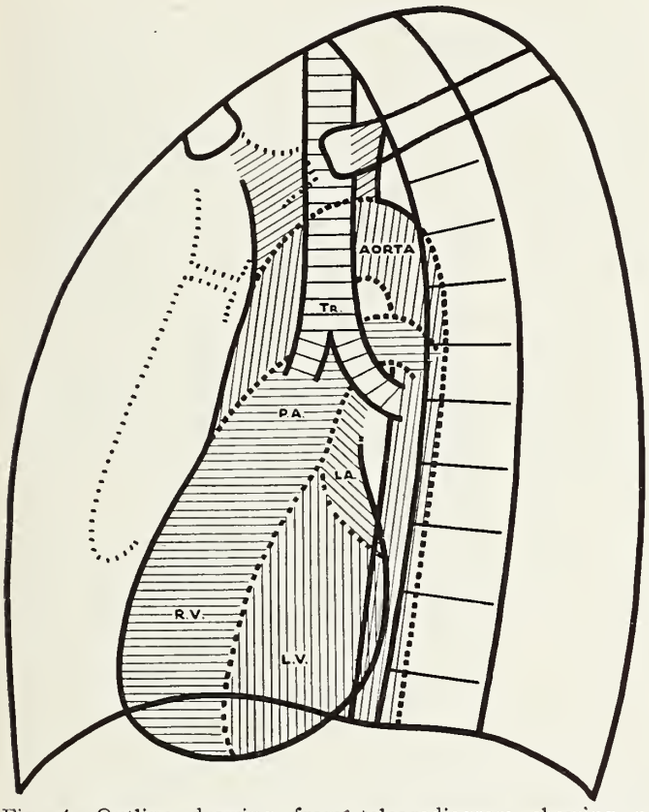

Fig. 4. Outline drawing from teleoradiogram showing normal relationships of cardiac chambers and great vessels. In left (II) oblique position (after Parkinson and Bedford).

Continuing the routine fluoroscopic examination, the patient is now turned half right and examined through the left side of the chest (Fig. 4). It has been said that this radioscopic view will eventually prove to be most valuable in studying cardiac enlargement. Here, the cardiac shadow appears as if the heart were cut in sagittal section. In this view it is possible to closely estimate the position of the interventricular septum. The ventricles make up approximately two-thirds of the cardiac silhouette, the shadow of the right ventricle in front and the left ventricle posteriorly. Normally, the posterior border of the left ventricle stands well away from the spine. The stem of the pulmonary artery is fairly well visualized in this view. The aortic arch is well seen sweeping up and posteriorly. This is an excellent view in which to study pathologic changes that occur in the aorta; namely, those due to arteriosclerosis, hypertension, syphillis and congenital defects.

An important landmark in the left oblique position is the "aortic window" (Fig. 5). It is bounded superiorly by the inner concave border of the aortic arch and inferiorly by the roof of the left auricle and posteriorly by the descending aorta. Under normal conditions it is fairly well illuminated. Crossing it is the left branch of

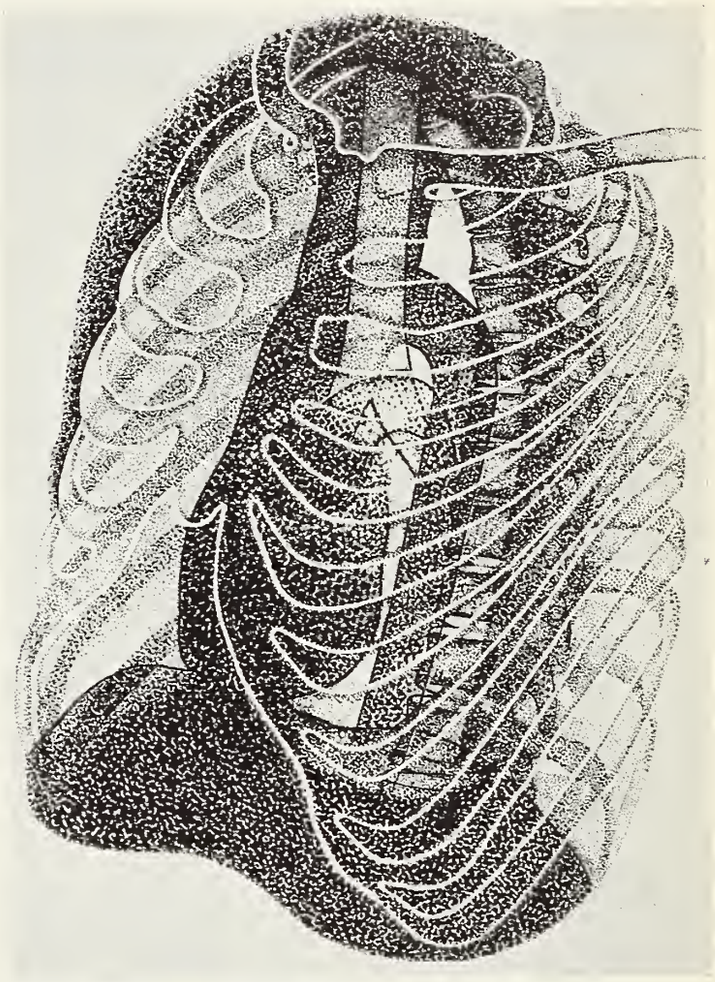

Fig. 5. Special drawing of normal teleoradiogram in the left (II) oblique position, to show the aortic window and superaortic triangle (after Parkinson and Bedford).

the pulmonary artery and in it lies the left main bronchus. In pathologic states such as hypertension and arteriosclerosis of the aorta it enlarges. In massive enlargement of the pulmonary artery, especially its left branch, the window is obliterated. In enlargement of the left auricle it is made smaller and the left bronchus is elevated.

Recently, Parkinson and Bedford have described a new radiologic landmark in the left oblique position (Fig. 5). This is a translucent triangle seen surmounting the upper border of the aortic arch when the subject is rotated 45° or more. The anterior border is formed by the left subclavian artery, the posterior border by the spine, and the base by the roof of the aortic arch. The aortic triangle is diminished by elevation, elongation, or dilatation of the aortic arch. An intrathoracic goitre or aneurysm of

the arch may encroach upon it. The triangle is enlarged by conditions which lower the aortic summit and by emphysema. By utilization of the base of the triangle as the upper point and the roof of the aortic window as the lower point of measurement, the measurement of the diameter of the arch of the aorta is often possible.

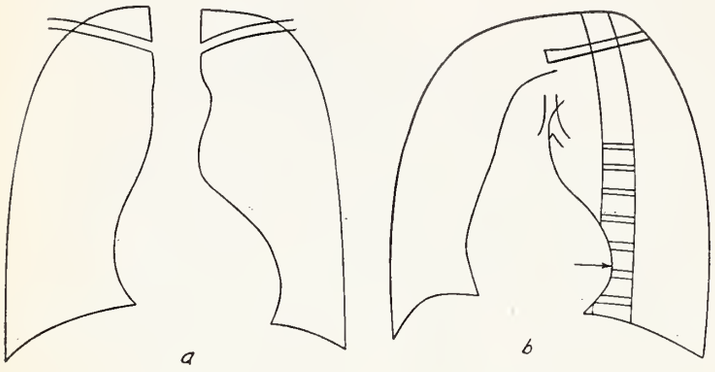

Fig. 6. Outline drawings from case of aortic stenosis in young male, aged twenty-two, blood pressure 108/87. Systolic thrill over aortic area. Harsh systolic murmur over aortic area transmitted to vessels of neck. (a) anterior view: aortic configuration with slight enlargement of left ventricle downward and to the left. The globular appearance suggests marked hypertrophy with slight dilatation. Fluoroscopic examination showed diminished pulsatory amplitude, tardus in character, of left ventricle and aortic shadow. (b) Left oblique view: left ventricle border projecting into the vertebral shadow.

Left Ventricle.—The most vulnerable of all chambers of the heart to enlargement is the left ventricle. Fortunately, from a radiologic viewpoint, enlargement of this chamber is comparatively easy to recognize. The difficulty lies not so much in determining whether or not the left ventricle is enlarged but in deciding whether it is simply displaced to the left. As already stated, the apparent size of the left ventricle depends much upon the position of the diaphragm. Furthermore, considerable enlargement of the right ventricle, particularly from right-sided congenital lesions, can displace the left border outwards, giving one the impression that the left ventricle is enlarged. However, this point can be settled by turning the patient well into the left oblique position (left shoulder to the screen). When the left ventricle enlarges it does so posteriorly as well as laterally. If, in this view, the posterior border of the left ventricle extends beyond the anterior shadow of the spine it is to be considered enlarged. However, if it stands clear in front of the spine the apparent enlargement seen in the anterior position is in all probability a result of displacement rather than enlargement.

It is difficult, if not impossible, to recognize hypertrophy by radioscopic examination. It is only when dilatation has supervened upon the hypertrophy that the increase in the size of the left ventricle can be recognized with certainty.

The aortic valvular lesions which produce left ventricular enlargement are aortic stenosis, either

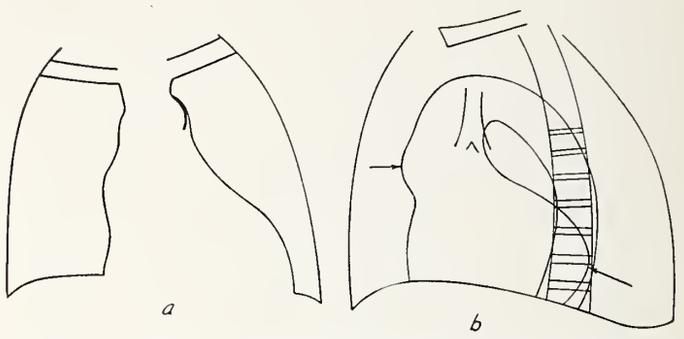

Fig. 7. Outline drawings from teleoradiograms from case of syphilitic aortitis and aortic incompetence. (a) Anterior view: large left ventricle, prominent ascending aorta which is irregular in outline and prominent aortic knuckle. (b) Left oblique view: Cardiac silhouette extends far into shadow of spine—left ventricular enlargement. Widened ascending aorta with localized outpouching.

arteriosclerotic or rheumatic in origin, and aortic incompetence which may be due either to rheumatism or syphilis. Isolated aortic stenosis alone, as a rule, causes only moderate enlargement of the left ventricle (Fig. 6 a and b). Left ventricular enlargement due to arteriosclerotic stenosis of the aortic valves can at times be differentiated from that due to rheumatism by radioscopic examination. The differentiation lies in recognizing calcification of the aortic valve and calcification of the aortic arch in arteriosclerotic stenosis. Furthermore, in aortic stenosis due to arteriosclerosis, the aortic knob is quite prominent, and the arch of the aorta can be seen to appear as ectatic. Aortic incompetence can be differentiated from aortic stenosis without any difficulty by the character of the pulsations of both the aorta and left ventricle. In aortic stenosis the pulsations of the heart and aorta are small. In aortic incompetence as a result of a high pulse pressure, the amplitude is great. X-ray examination also can help in differentiating aortic insufficiency due to syphilis from that due to rheumatism. An aneurysm or out-pouching of the aortic arch speaks in favor of syphilis (Fig. 7 a and b). Syphilis of the aorta without involvement of the aortic valves is practically never a cause of cardiac enlargement.

Hypertension, whether primary or secondary, affects the left ventricle. The degree of enlargement depends on several factors; namely, the height of the diastolic pressure, age, constitutional type, and presence or absence of coronary

disease. In the typical case the left ventricle enlarges in a boot-shaped manner and rather characteristic changes occur in the aortic arch. The aorta becomes uncoiled in that it diffusely dilates and elongates toward the root of the neck. This can be demonstrated in the left oblique view. The effect of this alteration is to increase the size of the aortic window.

Radiology is of invaluable aid in diagnosing congenital anomalies of the aortic arch. Persistent right-sided aortic arch can be diagnosed only by this method. The barium-filled esophagus can be seen to impress the arch on the left side instead of, as it normally does, on the right side, and the concavity of the aortic arch impression is directed to the right. Frequently, complete or partial coarctation of the aorta can be recognized by radioscopy. In this condition, a narrowing of the aortic arch just distal to the subclavian artery can sometimes be demonstrated (Fig. 8). The presence of hypertension in young adults should immediately suggest the possibility of coarctation of the aorta and the classical radioscopic findings which attend it should be sought.

Now that coronary thrombosis is so frequently recognized as a clinical entity, the complications that follow it can be determined with a fairly high degree of accuracy. Thus, formerly the diagnosis of cardiac aneurysm was relegated to the pathologist. It is now possible, by x-ray examination, to visualize the aneurysmal bulge in a fair proportion of cases. The common site for the development of the aneurysm is in the vicinity of the apical portion of the left ventricle for anterior infarction and along the posterior wall with posterior infarction. In both instances these aneurysms are radioscopically visible. We have recently observed an aneurysm of the lower posterior portion of the left ventricle when the patient was placed in the left oblique view. Roentgenological diagnosis of aneurysm of the heart is quite impossible when the lesion develops at the diaphragmatic surface or when it affects a septum. Calcification may occasionally be noted in the wall of the aneurysm.

Left Auricle.—Radiologic examination of the left auricle has contributed greatly not only to the recognition of mitral stenosis but also to a study of its effects on the enlargement of other cardiac chambers. Anatomically, the left auricle is situated entirely on the posterior aspect of the heart. For this reason it just rests against the esophagus. It is not visible from the front, except a tiny portion of it which is known as the left auricular appendage. It is therefore beyond the reach of percussion.

Fig. 8. Coarctation of the aorta, partial, in female, aged thirty-two, who died of subacute bacterial endocarditis. Outline drawing from teleoradiogram in left oblique view, showing kink-like narrowing of aorta. Considerable dilatation of aorta proximal to site of stenosis. Postmortem control.

According to Assman,[1] the right oblique position (patient facing examiner with right shoulder to screen) with rotation about 70° is the most favorable position because then the retrocardiac space is well shown, being bounded above and below by clear spaces Parkinson has stated that next to the presystolic murmur, the posterior displacement of the barium filled esophagus is the best evidence for left auricular enlargement in mitral stenosis (Fig. 9a and b). The stages of left auricular enlargement from one of simple enlargement to where it has assumed aneurysmal size and extends into the right chest can be easily demonstrated by radioscopy.

It should be pointed out here, however, that displacement of the esophagus is not pathognomonic of mitral stenosis. Babey[2] has recently shown, in radioscopic studies confirmed by necropsy findings, that other conditions may displace the esophagus posteriorly. Long standing cases of auricular fibrillation without mitral stenosis eventually lead to left auricular enlargement. In complete heart block the left auricle sometimes becomes quite prominent. A greatly enlarged left ventricle not infrequently can push the left auricle posteriorly. In such cases the barium-filled esophagus convexity in the right oblique position is often long and gradual and not so abrupt or placed so high as in the left auricular enlargement found in mitral stenosis.

Right Auricle.—The right auricle forms the right lower border of the heart and is therefore clearly visible from the front. When enlargement appears on the right side of the heart, it

should not be inferred that the right auricle is enlarged because lesions responsible for right auricular enlargement are rare. Enlargement in the region of the right auricle should rather indicate displacement of the heart, dextrocardia, enlarged left auricle extending out from behind the right auricle, generalized enlargement of the heart, pericardial effusion or aneurysm of the ascending aorta. These conditions can all be differentiated by radioscopic examination. Lesions affecting the tricupsid valve are rare. However, when tricupsid stenosis does occur, enormous enlargement of the right auricle ensues. In organic tricuspid incompetence or more commonly in relative tricuspid insufficiency, some enlargement of the right auricle is expected. This condition can occasionally be seen in advanced stages of pulmonary disease in which the right heart alone is affected. In congenital defects of the auricular septum, the right auricle is often enlarged to a considerable extent, especially when there is a coexistent congenital mitral stenosis. Rarely, isolated enlargement of the right auricle may be seen in congenital auricular septal defects, in the absence of other congenital anomalies.

Fig. 9a Fig. 9b Fig. 10

Fig. 9. Mitral stenosis and aortic insufficiency, auricular fibrillation in male, aged forty-seven. (a) Left oblique view. Right ventricular enlargement shown anteriorly. Left ventricular enlargement indicated by cardiac shadow projecting into the shadow of the spine. The left bronchus is elevated by an enlarged left auricle. The aortic window is narrowed. (b) Right oblique view. The enlarged left auricular (balloon-like prominence) displaces the barium filled esophagus posteriorly and obliterates the retrocardiac space. Anteriorly, there is considerable prominence of the pulmonary conus. Just below this is noted a bulging of the mass of right ventricle which almost completely obliterates the lower portion of the anterior mediastinal space.

Fig. 10. Teleoradiogram, right oblique view, showing enlargement of the conus region of right ventricle. From case of emphysema. Postmortem control.

It should be further mentioned that long-standing cases of auricular fibrillation will, in time, cause enlargement of both auricles. By studying the radioscopic impressions of the barium-filled esophagus it is possible to differentiate left auricular enlargement from right auricular enlargement.

Right Ventricle.—Radiology has rendered a great service to cardiology in facilitating the recognition of right-sided lesions. In the study of enlargement of the right ventricle it is important to recognize the fact that the outflow tract of the right ventricle represented by the conus is the first to suffer enlargement from whatever may impose a strain on it. Fortunately, conus enlargement can be recognized in its early stages. First evidence of conus enlargement is best seen in the right oblique view with the patient well turned to the left (Fig. 10). In this position one sees a localized outpouching between the shadow of the pulmonary artery and the body of the right ventricle. When the enlargement becomes more pronounced, the conus becomes radioscopically visible on the left border of the heart in the anteroposterior view. With subsequent involvement, the body of the right ventricle becomes implicated and can be recognized best in the left oblique view (Fig. 9a). This is best demonstrated when the patient is turned well to the right (about 60°). Certain right-sided congenital lesions have fairly definite radiological appearances. By correlation of the shape of the heart with the auscultatory findings and the presence or absence of cyanosis it becomes possible to determine the location of the lesion with great accuracy.

Congenital heart lesions should no longer be looked upon as a matter of purely academic interest because, as Maude Abbott has shown, the prognoses in many types of congenital anomalies are extremely favorable. It is, therefore, important to recognize the type of congenital anomaly of the heart before venturing a poor prognosis. Radiology serves to distinguish congenital

lesions from rheumatic valvular defects, occasionally a difficult task from purely clinical observations. The Tetralogy of Fallot, one of the common causes of cyanosis in congenital heart

Postmortem control.

disease, often gives a characteristic cardiac silhouette, namely a dextroposed aorta, small or normal sized pulmonary artery, and an enlarged right ventricle. Patent ductus arteriosus with a small aorta and dilated pulmonary artery and conus usually offers no difficulty (Fig. 11a and b).

Further contribution of the radioscopic method to the study of cardiac enlargement has recently been submitted by Parkinson and Hoyle[12] in their comprehensive treatise on the heart in emphysema. So convincing is their evidence that one need no longer doubt that the right heart is involved in this disease. In our studies on emphysema heart we have been able to confirm their findings. They have pointed out that cardiac measurements are invalidated because of the excessive width of the chest in emphysema. They further emphasize that the signs of right ventricular enlargement are different and elusive, being not nearly as easy to recognize as the signs of left ventricular enlargement to which physical signs are so largely directed.

Right ventricular enlargement in emphysema is most commonly recognized by the prominence of the conus which may be seen from the front but better yet in the right oblique view (Fig. 10). It has been shown by Kirch[7] that the far end of the outflow tract of the right ventricle, the conus, suffers first from increased pressure in the pulmonary circulation. The conus first lengthens rather than widens, and this is frequently overlooked if one expects to find an increase in the transverse diameter of the heart seen from the front. While the prominence of the conus is more common and exaggerated than enlargement of the body of the right ventricle, nevertheless, enlargement of the right ventricle can best be seen with the subject rotated in the left oblique position to about 60°, where it forms the anterior border of the silhouette.

Another radiologic feature of emphysema heart is prominence of the pulmonary artery seen from the front (Fig. 12a). Here also, dilatation of its branches can be visualized. Prominence of the main pulmonary stem can be recognized roentgenologically in the two oblique positions (Fig. 12b). In the left oblique the stem and left main branch can be seen as one of the structures lying in the aortic window. Not infrequently the pulmonary artery may become enlarged to entirely obliterate the window. With barium paste, the so-called right pulmonic artery impression can be recognized on the esophagus. In enlargement the pulmonary artery impression becomes exaggerated.

A marked prominence of the pulmonary artery and conus or one of the main branches has often been erroneously interpreted as mediastinal tumor. Pulmonary artery enlargement is commonly observed in certain types of congenital defects: namely, in patent ductus arteriosus; auricular and ventricular septal defects; and in congenital aneurysm of the pulmonary artery or one of its branches. Among the acquired lesions that cause pulmonary artery enlargement are mitral stenosis, especially when associated with pulmonary valve incompetence, congestive fail-

ure, chiefly of the left ventricular type, and enlargement in the early stages of hyperthyroid heart (Fig. 13a and b). The pulmonary artery is likewise enlarged in pulmonary arteriosclerosis

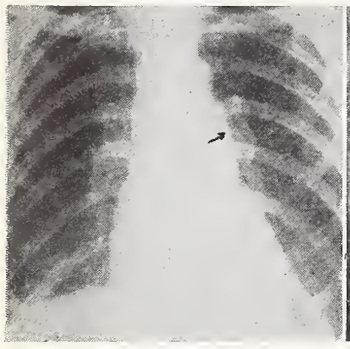

Fig. 13a

Fig. 13b

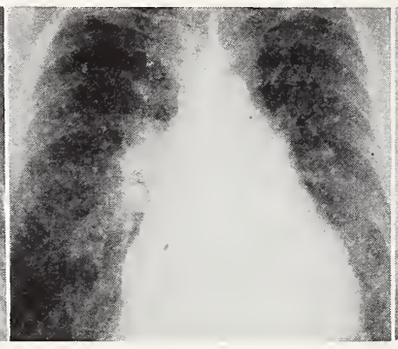

Fig. 14a

Fig. 14b

Fig. 13. Toxic adenoma in female, aged forty-eight. BMR + 68 per cent. Tachycardia, palpitation, and dyspnea on exertion. First sound at apex booming in character (pseudo-mitral stenosis). Harsh systolic murmur over pulmonic area. Teleoradiogram: (a) Anterior view: Prominence of pulmonic arch. No cardiac enlargement. Radioscopic examination showed hyperactive pulsations along all borders, particularly the pulmonary artery. (b) Right oblique view showing pulmonary artery prominence.

Fig. 14. Pulmonary arteriosclerosis in male, aged thirty-three. Only complaint is dyspnea on moderate exertion. Systolic murmur heard over pulmonic area. No diastolic murmur heard. Second pulmonic sound accentuated. Venous pressure normal. Circulation time: from arm to lung somewhat prolonged, twelve seconds. Circulation time: from lung to tongue normal. In the anterior view, the striking feature on radioscopic examination was the hilar dance (expansile pulsations of pulmonary stem and its branches). The smaller pulmonary vessels out further in the lung fields could also be seen pulsating noticeably. Pulsations at the left lower border of cardiac silhouette is the right ventricle. These pulsations alternate in direction (see-saw movement), with pulmonary arch. Teleoradiogram: (a) Marked enlargement of cardiac silhouette. Chiefly right ventricular enlargement, with prominence of pulmonary arc. Aortic shadow not seen. Pulmonary arterial branches markedly enlarged. (b) Right oblique view: Mass of heart chiefly right ventricle. Left atrium not enlarged. The dense, bandlike shadow (indicated by arrows posteriorly) is the shadow of the dilated right main pulmonary artery. The left oblique illustration is omitted. It showed the aortic window filled out by the pulsating shadow of the pulmonary artery. There was very little, if any, enlargement of the left ventricle posteriorly. Anteriorly, enlargement of the body of the right ventricle was pronounced.

and rarely in syphilis of the pulmonary artery. The so-called hilar dance and pulsations of the pulmonary vessels are irrefutable evidence of pulmonary artery enlargement (Fig. 14). By radioscopy it is possible to distinguish cardiac enlargement from pathological conditions in the mediastinum or in the surrounding structures that may simulate cardiac enlargement, such as mediastinal masses, lung tumors, and spinal cord tumors. Differentiation is made possible by rotating the patient behind the fluoroscopic screen. In this manner extra-cardiac shadows can be separated from the silhouette of the heart.

Constrictive pericarditis.—There is one type of chronic heart disease in which surgery is unquestionably indicated and when carried out successfully leads to dramatic recovery. I am referring to chronic constrictive pericarditis, fifteen cases of which were reported by Paul White[15] in the St. Cyres lectures in 1936. He described the condition as one of a state of congestion without cardiac failure, which was brought about by a thick, rigid wall of pericardium surrounding the heart and the great vessels, in this manner embarrassing its action and mechanically obstructing the inflow of blood.

In discussion of his cases, he stated heart disease was a rare association and that rheumatic fever was not an etiologic factor. The findings of mitral stenosis ruled out its presence. The cardiac shadow was normal in size in seven, slightly enlarged in five, and moderately enlarged in three cases. In the case of constrictive pericarditis that we have recently studied the heart was normal in size. The clinical manifestations of chronic cardiac compression are distended cervical veins, cyanosis, ascites, enlargement of the liver, edema and hydrothorax, pulsus paradoxus, small pulse and low pulse pressure. However, before decortication of the heart is attempted, the clinician must make doubly sure that the constrictive phenomena exist. The opportunity to confirm the clinical findings is made possible by radioscopic examination. In this condition we usually see a normal sized heart which is fixed in position. The striking feature is that the heart is immobile. The act of respiration does not alter its size nor shape. Frequently, no pulsations of its borders can be discerned. If pulsations are present, they are markedly impaired and localized either to the right or left side of the heart. Occasionally, areas of calcification can be visualized in the thickened pericardium. The results reported by Churchill[4] and Beck[3] after performing pericardial resection are indeed striking and stand out among the great achievements of modern surgery of the heart.

Time will not permit me to discuss any fur-

ther the usefulness of radioscopy to clinical cardiology. The clinician who has the radioscopic method at his disposal is equipped with a diagnostic facility equal to if not greater in importance than the electrocardiogram. Briefly, the radioscopic method gives us the following information. It replaces percussion and palpation because it gives the extent of cardiac enlargement with a much higher degree of accuracy. By the radioscopic method it is possible to determine slight changes in heart size and to distinguish whether, in doubtful cases, the heart is normal or enlarged. While it is possible that the cardiac silhouette is sometimes less informative than auscultation, as, for example, in early cases of mitral stenosis, aortic insufficiency and certain congenital defects, it gives us superior information regarding prognosis. Other things remaining equal, the smaller the cardiac silhouette, the better the prognosis. By the radioscopic method it is possible to recognize alterations in the shape of the heart. These alterations in shape inform us as to which chambers are involved, and to what extent, and give us a clue as to the etiologic basis for enlargement.

In conclusion, I would like to quote Dr. John Parkinson,[10] who comments about the present and future status of radiocardiology:

"Radiology can contribute to direct and exact knowledge in almost every variety of cardiac disease. . . . Though some will doubtless exaggerate its importance, it will steadily find its proper level among modern means of diagnosis. It is natural to regard with suspicion anything unfamiliar, and it is our duty to scrutinize any new method; but let not this defer our acquaintance with radiology of the heart—a novetly no longer. The modern physician will have his diagnostic powers extended and refined by adding radiology to his scheme of examination; he will supplement traditional methods by direct inspection of the internal organs. . . . Cardiology is now an important and integral branch of general medicine, nothing more and nothing less. It will advance and develop beyond a post-mortem pathology which is static. By radiocardiology we shall reach a more vital anatomy and physiology, and—earlier in disease—a dynamic pathology of the living heart."

CONGENITAL SYPHILIS*

Analysis of the Problem in Minnesota

FRANCIS W. LYNCH, M.D.
Assistant Professor, University of Minnesota
Saint Paul, Minnesota

RECENT interest in the prevention and control of syphilis should be accompanied by increased attention to congenital syphilis because it is a phase of the disease entirely controllable by prophylactic measures. Preventive therapy is almost uniformly successful after the early recognition of maternal syphilis by routine serologic studies of pregnant women. Since these preventive measures are not of recent development but have been recognized for twenty years, one may well inquire why additional cases of congenital syphilis are continually seen.

Although congenital syphilis is not a major public health problem in Minnesota it is interesting to note that over a ten-year period there is no appreciable change in the number of reported cases of this disease†

1927	125	1932	105
1928	67	1933	151
1929	103	1934	131
1930	163	1935	122
1931	134	1936	105
1927-1931	—592	1932-1936	—614

The statistics for the two five-year periods are perhaps not comparable inasmuch as the profes-

*From the Division of Dermatology, University of Minnesota Medical School, Dr. H. E. Michelson, Director.

†Figures obtained by courtesy of Dr. O. McDaniel, Minnesota State Board of Health.

sion has been more alert in recognizing syphilis in recent years and much more prone to report new cases to the State Board of Health. It is possible that there has been an actual decrease in the incidence of congenital syphilis.

It was thought that analysis of the new cases recently observed at the University and Ancker Hospitals might disclose the reasons for the continued occurrence of congenital syphilis and point out a course to follow in future attempts to prevent this disease. During a period of two years a total of thirty-seven congenital syphilitics made their first visit to these two clinics. An additional fourteen patients were included in the study because they presented manifestations of active syphilitic infection during this period although the diagnosis had been made in previous years. In approximately one-third of the total cases, the physician or agency referring the patient to the clinic had already established the diagnosis.

	Ancker	Univ. Hosp.	Total
Cases studied	26	25	51
New cases in two-year period	21	16	37
Diagnosis known before admission	9	9	18 (35%)

Since the symptoms of congenital syphilis are well known the clinical investigation of this series was limited to a simple classification. The patients classed as suffering from early signs of congenital syphilis included examples of snuffles, rhagades, osteochondritis and cutaneous eruptions. It is unfortunate that in so many as twenty-two cases the disease was not recognized until the development of neurosyphilis or interstitial keratitis, conditions where treatment seldom returns the tissues to completely normal function.

Clinical manifestations	Ancker	Univ. Hosp.	Total
Early	5	7	12 (24%)
Asymptomatic	12	5	17 (33%)
Interstitial keratitis	5	7	12 (24%)
Neurosyphilis	5	8	13 (26%)

(Three children had both keratitis and neurosyphilis)

The relatively large number of children showing no clinical evidence of congenital syphilis is evidence of some progress toward lessening the damage resulting from this disease. Only a few of these children were referred to the clinic as a result of routine serologic studies. Most of them were members of families where the diagnosis of syphilis had been made on another individual a short time before. The entire family was then investigated and in the case of these children the disease was recognized before serious pathologic changes had taken place. It is unfortunate that a still larger number of cases could not have been recognized while the infection was still asymptomatic.

In the case of syphilis as with most other infections the chance for cure is much greater when the infection is recognized early. In an attempt to determine the amount of time lost before proper diagnosis, these patients were grouped according to their ages at the time of diagnosis. In nearly half the group the children were of school age before the disease was recognized.

Age at time of diagnosis	Ancker	Univ. Hosp.	Total
Under 6 months	8	8	16 (32%)
6 months to 6 years	6	5	11 (22%)
6 years to 10 years	7	4	11 (22%)
Over 10 years	5	7	12 (24%)

Congenital syphilis presents a minor problem in Minnesota in comparison with many other communities, but in spite of the relatively favorable nature of the local situation thirty-seven new cases of this preventable disease have been observed at Ancker and University Hospitals within a two-year period. As it is unreasonable to expect complete eradication of congenital syphilis or any infectious disease, the question arises whether its incidence has reached an irreducible minimum in Minnesota. In the light of experience elsewhere, particularly in the Scandinavian countries, this question must be answered in the negative.

This state has been fortunate in the efforts of the State Board of Health in the control of syphilis and in the manner in which the public clinics have performed serologic tests on all pregnant women. The dermatologic and obstetric clinicians at the Medical School have taught for many years that every pregnant woman, whether in a clinic or under private care, should have a Wassermann test early in each pregnancy. The failure of many physicians to perform such tests is certainly not due to ignorance of their value but rather to discouragement after performing large numbers of such tests with only negative results. Nearly all physicians have known that intensive specific treatment is urgent after recognition of syphilis in pregnancy. Con-

genital syphilis is being observed in spite of this knowledge and must be regarded as a problem deserving further attention.

In the case of prevention of congenital syphilis, as in all medical advances, there has been a period of time, a lag, between the scientific discovery and its universal acceptance and application. To a certain extent such delay is inevitable, but every effort should be made to reduce it to a minimum. It was thought that study of the individual histories of these fifty cases of congenital syphilis might disclose information as to the cause of this "lag" and point out a course to follow in future efforts against the disease.

With reference to congenital syphilis the education of the medical profession has not been as successful as might be desired. It is evident that routine serologic study in pregnancy would result in almost entire prevention of the congenital infection but it is not clear in this group of cases how often the lack of this study was the fault of the attending physician. In one case, however, the presence of syphilis was demonstrated in the seventh month of pregnancy, yet the physician determined to "defer treatment until termination of the pregnancy" and a congenital syphilitic child was born. Another woman having neurosyphilis was admitted to a third hospital early in pregnancy. Although she was an inmate of this institution throughout her pregnancy, no specific therapy was given and a syphilitic child was born.

The physician has an added responsibility to avoid delay in diagnosis after the birth of the child. One infant suffered early from convulsions and at the same time presented a cutaneous eruption, yet the diagnosis was delayed until the child was seven months of age. A seven year old child gave a history of "sore eyes" since infancy but the cause was not recognized until after the development of neurosyphilis. A sixteen year old child had "always been sick" and the father was known to have syphilis but interstitial keratitis developed before the disease was recognized.

One woman had previously received inadequate treatment for syphilis yet no serologic study or antiluetic treatment was ordered during her pregnancy. Her child was sickly for the first few weeks and then failed to gain weight while the disease progressed until the child was admitted to the hospital at three months of age. In this case treatment had been delayed too long and the child died a few days later.

These instances are all evidence of the need for further education of the profession in the available scientific knowledge. Another example of professional failure occurred in an institution which requires Wassermann studies on all women delivered. In this case, although the test was probably performed, no report was recorded, since the patient's laboratory sheet was misfiled. Several months later the child returned with congenital syphilis and the oversight was noted. An occasional error of this nature is probably to be expected though not to be excused.

A second reason for "lag" in the application of medical knowledge is the time required for education of the public. It is evident that continued effort is necessary to persuade women to report to their physicians in the first few months of pregnancy. If maternal syphilis is recognized this early, the proper treatment is almost always successful in preventing congenital syphilis. The present extensive publicity campaign against syphilis may overcome some of the objections of women to submitting themselves to routine Wassermann studies in private practice.

Every syphilitic woman when starting treatment should be told of the importance of regular therapy during pregnancy and should be made to realize the necessity of notifying her physician early in subsequent pregnancies. Her Wassermann test may then be negative due to previous treatment, yet further treatment is indicated for prevention of infection of the child although the mother herself might not otherwise require this treatment. In several instances in this series the mother knew of her infection yet received little or no treatment during pregnancy.

Since a certain element in the population will never accept responsibility in matters of health, whether individual, family or public, it is evident that education without control will not be sufficient. It is particularly in these cases that public health workers must be interested and active.

Recognition of this public responsibility leads to study of the third cause for "lag" in the attempts at control of congenital syphilis. In many cases in this series the available social service or public health facilities were inadequate. It is to the credit of these workers that many of the cases of congenital syphilis were

brought to the clinics while the infection was asymptomatic or latent. Most of these asymptomatic patients represent brothers and sisters of previously recognized cases of congenital syphilis, or children of women in whom the disease was recognized long after pregnancy. The State Board of Control must also be credited with recognition of the disease before it was clinically evident in four of these children who were submitted for examination as candidates for adoption.

The following cases from this series are cited as examples of failure of social workers or public health authorities. In one case of interstitial keratitis and another with neurosyphilis, the mothers had been under treatment for syphilis for one year before the children were brought to the clinic for examination. In another case there was a similar delay but the consequences were less serious as the child suffered only from iritis. In one case of interstitial keratitis, four years were allowed to elapse between recognition of the disease and institution of treatment. In the interim an extensive cutaneous gumma developed. In the case of a very young infant, four months were lost after reference of the patient from the pediatric to the dermatology clinic before he reported for treatment. One unfortunate youngster developed interstitial keratitis six weeks after admission to the clinic. He was awaiting the completion of arrangements for his treatment. A child referred from the University Hospital to Ancker Hospital returned to the original clinic a year later without having reported at the Ancker Hospital. Neurosyphilis had been allowed to progress during this period of unnecessary delay.

The difficulty of placing on a single person or service the responsibility for the development and unrecognized progression of congenital syphilis is well indicated in the following history. A woman first seen in the clinic in July, 1933, was treated for gonorrhea but no serologic tests for syphilis were performed. She returned to the obstetric clinic two years later, when routine studies showed a positive Wassermann reaction but treatment was not instituted until seven weeks after her admission to a pre-natal clinic. The child was apparently normal at birth but was taken six weeks later to another hospital where clinical, serologic and roentgen studies showed him to be syphilitic and he was referred back to the original clinic for treatment.

Summary

Though only thirty-seven new cases of congenital syphilis have been observed in two years in the University and Ancker hospitals, it is evident that many of these could have been prevented. The scientific background for such prophylaxis is well established.

In this study an attempt has been made to determine the reason for failure of these preventive measures and in many of these cases it has been possible to place the responsibility for this failure. The examples which have been cited serve to show that future attempts toward the control of congenital syphilis require greater interest on the part of the medical profession and the provision of more adequate social service and health department facilities. Education of the general public appears to be a minor factor in the prevention of congenital syphilis.

The following procedures are suggested as methods for the prevention of congenital syphilis and its serious effects on the child:

1. *Every woman with gonorrhea should have a Wassermann test in order to recognize early many cases of syphilis which are now passing unrecognized.*

2. *Every syphilitic woman should receive adequate treatment but should also be warned of the need to report to her physician early in any subsequent pregnancy and inform him of her syphilitic status.* (A woman who has once had syphilis usually requires treatment throughout each pregnancy. Patients whose disease is of more than eight years' duration and who have received "adequate" treatment previous to the pregnancy may be exceptions to this rule.)

3. *Every pregnant woman should have a Wassermann test early in pregnancy.*

4. *After the diagnosis of syphilis is made during pregnancy, treatment should be intensive.* (If it is started in the third or fourth month and at least ten arsenical and ten heavy metal injections are given, a normal child may be expected. The dosage of the drugs and the division into courses are matters for individual arrangement.)

5. *At the time of delivery a Wassermann test should be performed on the maternal blood or the "cord" blood in every case.* (Collection of blood from the severed cord is a simple method

for determination of the serologic status of the mother only. Since the child's serologic identity is not established until several weeks after birth, a Wassermann test on cord blood does not prove the presence or absence of congenital syphilis. A positive Wassermann reaction on the cord blood, or the maternal blood, aids recognition of those cases in which syphilis has been acquired subsequent to the Wassermann tests performed earlier in pregnancy. Additional clinical, roentgenologic and serologic studies will establish the status of the child.)

If the medical profession were to follow these rules, even allowing for some lack of coöperation on the part of the patient, congenital syphilis could be practically eliminated in Minnesota. In the few cases where it might develop, the disease would be recognized and treated before irreparable damage was done.

PERSONAL SURGICAL OBSERVATIONS*

J. LAWRENCE McLEOD, M.D.
Grand Rapids, Minnesota

I WISH to present tonight a few observations on surgery in general as practiced by an average surgeon in a small hospital, and at the same time to report a few cases, each of which will, I hope, bring home some practical point.

It is my firm belief that those of us who practice in the smaller communities and institutions often give our patients closer individual service and attention and hence obtain better results than may be obtained in larger and better advertised surgical centers. In the larger centers the surgeon is likely to do less and less for the patient aside from the operation. Unless grave emergencies arise, the surgeon sometimes never sees the patient either before or after he meets him at the operating table, the operation often having been arranged for by the house staff alone. This is an additional wrong.

The closeness of personal contact between patient and surgeon so pleasant and profitable to both, which once prevailed even among busy surgeons in large centers has been largely disrupted, to the loss of both. The surgeon gains a little leisure and saves some wear and tear. The patient loses the solace and comfort he has a right to expect. *The two do not balance!!*

My personal opinon is that the operation itself is the least important to the patient's welfare, the preoperative and postoperative care far outweighing in benefit to the patient the actual technic.

Preoperative Care

I shall dwell but a few moments upon this feature.

1. Patients who face any major surgical procedure are entitled to and should receive a full and careful physical check-up in the home or office before ever arriving at the hospital.

Any and every abnormality revealed or even suspected from the history or examination should be carefully checked into, and, if possible, remedied before the patient goes to the hospital.

I vividly recall a patient seen by two of us who suffered from recurrent attacks of angina pectoris. We had seen him in several attacks and had treated him and brought him out. The man was not satisfied and went away to a large Clinic. The Clinic got an indifferent history, gave the man a routine check, told him he had gallstones, and diagnosed his previous spells as gallstone colic. The man had his gallbladder removed (fortunately did not have an angina spell while in the hospital) and returned home only to have another angina spell in which he died. In my mind, the operation contributed to his untimely end. A thorough check-up with full history and coöperation between that Clinic and the home doctors would have been of considerable value.

2. The patient's chief resources on entering the operating room are his constitutional powers and his resistance, reinforced by cheery bravery; and all that can be done to increase these should be done. I have in mind two specific cases in which death postoperatively occurred partly, at least, because of lack of reserve.

One case was a woman who had been for some

*From the Itasca Clinic. Read before the Itasca Hospital Staff, Grand Rapids, Minnesota, September 2, 1937, and before the Range Medical Society, Virginia, Minnesota, October 19, 1937.

time on a self-imposed restricted diet on which she lost twenty-five pounds from a normal weight of 160 pounds. She thought this would cure her gallbladder attacks and increase her beauty. Operation became imperative because of rapidly recurring attacks of colic and intractable vomiting, but the woman just faded out of the picture postoperatively because of lack of stamina.

A second patient, a strong, able-bodied and apparently robust young woman, was run down, however, from five pregnancies, the care of a large family and repeated gallbladder colic. Her examination revealed no really great physical handicap. After thirty-six hours in the hospital, during which time she rested well and was well checked, her gallbladder was removed. Thirty-six hours after the operation she developed a cardiac failure and died.

In both of these cases, a preliminary period of preparation with rest and general care might have spelled a different final result. It is unnecessary to go into great detail but there are a number of conditions such as anemia, jaundice, elevated blood pressure, obesity and alcoholism which require preliminary treatment prior to operative procedures.

3. Hospitalization for at least twenty-four hours prior to all major operations gives the patient a chance to become accustomed to new surroundings, nurses, attendants and hospital procedure. It further gives the sincere surgeon a chance to gain the patient's additional confidence and allay nervous misgivings. The preanesthetic preparation too can be performed in a more thorough and leisurely manner. This will all contribute to a better final result and it is our experience that a quiet day or two in the hospital before a major operation is *not* an additional expense because it will reduce the postoperative hospitalization a corresponding amount.

Let me say also that the old-time habit of giving laxatives preoperatively is a vicious practice. Unless the operation is for hemorrhoids or extensive perineal work, I can see no justification for causing the patient the fatigue of a day's diarrhea with its accompanying cramps, its tendency to produce gas pains and distress on succeeding days, and, above all, its dehydration, which is the very thing every surgeon should avoid. How utterly silly it is to give a purge which dehydrates and then intravenous fluid just before or after operation to counteract dehydration. One has only to recall many appendectomies done without even a preliminary enema, which have resulted successfully, to understand the foolishness of this practice.

4. Every surgeon has his own pet theory about anesthetics and the preparation therefor. I shall not attempt to discuss any. Suffice it to say that once a regular routine has been tried and proven, it should be carried through in all cases and a surgeon in a small community has no right to attempt to make guinea pigs out of his patients with a lot of untried or half proven new drugs which some irresponsible agent tries to sell him.

So much for preoperative care.

Postoperative Complications and their Treatment

I quote:

"Many a well-fought surgical battle, won on the operating table, is needlessly lost in the convalescent room. The surgeon should personally attend to postoperative directions. There is too great a tendency to operate and get out—rather than operate and stay about.

"Many a cleverly performed operation has passed into death through faulty and inefficient after-treatment—while many a desperate and apparently hopeless operation has gone into brilliant recovery through after-treatment skill and efficiency. A patient may be put upon the road to recovery by operation—but unless he be wisely guided along that road, the operation may be unavailing. Even a bungled operation with a safe, speedy convalescence and satisfactory outcome, is more, far, to the patient than the cleverest operative technic followed by a long, painful, or hazardous, convalescence, and with an imperfect result.

"The surgeon's work and responsibility are only partly done when he has finished operating. Often much more judgment, and higher and broader surgical qualifications, are needed in the early recognition of conditions following operations, and in the after-guidance of those conditions to safety and full function, than was ever demanded in the mere operative technic. The surgeon who is an excellent operator but an indifferent postoperative fighter will probably lose more patients than the indifferent operator who is a hard and efficient postoperative fighter."*

The patient on return from the operating room and following recovery from the anesthetic should be allowed every possible freedom of position consistent with comfort. A pillow under the knees renders the abdomen less rigid and hence more comfortable. The postoperative nausea and vomiting are seldom prolonged and

*Bickham, Warren S.: Operative Surgery, Philadelphia: W. B. Saunders Company, 1924. Volume I, page 289.

as a rule take care of themselves or the cause is apparent and the condition corrected by simple means. One very common postoperative error is wrapping the patient too warmly and causing excessive dehydration by sweating. Where possible, the patient should not be allowed to sweat excessively either on the operating table or after return to bed. What possible excuse can there by for proctoclysis, hypodermoclysis and intravenous therapy to restore the fluid balance if we at the same time permit dehydration by a hot pack of wool blankets and hot water bags?

I am happy to note also that, with the exception of operations on the stomach and duodenum, the patient is today allowed to have fluids practically *ad lib.* following operation. I feel that many cases of gas pains and general distress can be completely avoided if the patient is encouraged to take nourishment in moderate amounts following almost all operations where the anesthetic has not caused unfavorable reaction.

Postoperative pain should be absolutely controlled for two or three days by large enough doses of an opiate to really do some good. Postoperative bleeding should always be investigated and the cause removed. Postoperative shock should not occur if the patient has been properly prepared and the operative procedure is within the physical strength of the patient. I believe no surgeon should plan to operate longer than two hours at any one stage. The patient just is not made to stand that prolonged shock to the nervous system under any type of anesthesia. If shock does occur, it must be combated with every device at the surgeon's command.

The major postoperative complications which I wish to discuss and illustrate with case reports are:

1. Pulmonary embolism.
2. Acute gastric dilatation (gastric paresis).
3. Obstruction.
4. Paresis and paralysis of the bowel.

Pulmonary Embolism.—This frightful specter rears its ugly head following surgical procedure every so often. There is no proven cause for it and no known prophylaxis or treatment. My single case is:

A woman, forty-six years of age, a hard-working farmer's wife, had for a good many years suffered from a large adenomatous goiter and recurrent gallbladder attacks. About three years before she had come to the hospital for cholecystectomy she had shown signs of marked hyperthyroidism. She refused treatment and allowed the toxins to do their damage for two years before she finally went to the University Hospital, where a successful thyroidectomy was done.

Her gallbladder symptoms had started to be more severe and frequent about the same time but we waited a year before suggesting gallbladder surgery. The gallbladder was readily removed and the patient convalesced satisfactorily although she was nervous and somewhat apprehensive. On the morning of the fourth day, the patient remarked to the nurse that she felt "better than she ever felt in her life." She requested a bed pan. The nurse got one, returned, helped her on the pan only to have the patient collapse and die in a few seconds.

Ingleby says of this condition:

"The patient who may be convalescing from an operation or apparently in good health suddenly becomes dyspneic and cyanosed. Death may be practically instantaneous. Survival is rarely as long as 10 minutes."

Inasmuch as we know of no prophylaxis and no treatment, the case is reported merely as one reason why a surgeon should always give a guarded prognosis and keep the back door open for a rapid run to cover in the face of such rare but always possible eventualities.

Postoperative Acute Gastric Dilatation.—This condition is also rare but its occurrence is frequent enough and serious enough to demand the most active measures for relief without which death usually occurs within twenty-four to forty-eight hours. It occurs in the second twenty-four hours following operation and it should be especially remembered that it may occur in connection with extra-abdominal as well as intra-abdominal operations. It has also been encountered in connection with various non-surgical conditions such as pneumonia and typhoid fever. Its cause is unfortunately not definitely known. but it appears that an atonic state of the stomach and overfilling of the organ with food or fluid play a part. Toxemia, an unusually long mesentery, duodenal obstruction and the like, have also been blamed.

A case in point was that of a young man of twenty-five years who, on August 4, 1937, at 5 a. m., left Nashwauk for the Twin Cities. On the way down, he became ill with considerable abdominal distress, nausea and protracted vomiting. In spite of his illness he completed his business in the Twin Cities and then drove home via Duluth and the trip home took fourteen hours, much of the time being spent vomiting by the roadside. He arrived home at 2 a. m. but did not

see any physician till 4 p. m., August 5, when we admitted him to the hospital. He had a ruptured appendix. He was operated at once, the wound being closed with drainage.

The first twenty-four hours postoperative were very quiet and seemed normal. At 7 p. m., twenty-seven hours after the operation, he suddenly began to be distressed. His lips and fingernails became cyanotic, his pulse increased rapidly in rate and became irregular, his breath came in short apparently painful gasps. There was not much apparent distension but the epigastrium became markedly tympanitic. A rectal tube brought a little gas but no relief. He did not and could not vomit. He could not void. There was a small amount of purulent drainage from the wound. His lungs, because of heart failure, started to fill with mucus and secretions, and he had the so-called death rattle. His condition became alarming by 10:30 p. m. Many attempts to introduce the nasal suction tube were not successful. We then decided to try the large stomach tube. This failed to go down and so embarrassed the patient that he almost expired.

Because of our inability to get suction started in the orthodox manner, the patient was turned and placed in knee-chest position with several pillows under the hips, the face out over the edge of the bed. In this position, we got our tube down and got results. The patient showed considerable improvement. Nasal suction was continued for two days. Digitalis was given for the heart. Enemas and rectal tube produced results, proving that we had no intestinal paresis. Intravenous fluids were given repeatedly.

During the third postoperative day, the pulse fell rapidly and the boy proceeded to make an uneventful recovery.

Postoperative Obstruction.—I shall here consider only mechanical obstruction and consider paresis separately. Mechanical obstruction seldom occurs immediately after operation. Our cases have been seen months following operation.

One such case was that of a young man seen in June, 1933, with an appendix which had been ruptured several hours. He was very ill. Decision was made to operate and establish drainage. The appendix was not looked for but the drainage was established, the bowels mopped up and 300 c.c. of normal saline left in the abdomen. He had a stormy convalescence but left the hospital on the twelfth day.

Subsequently, he had several minor and one major spell with obstructive symptoms. The administration of mineral oils helped him, but on January 24, 1934, seven months after the operation, he came back to the hospital acutely ill, greatly distended, vomiting profusely and in great pain. Enemas and nasal suction were of no avail so an operation was performed. The ileocecal junction was found bound down tightly and the small bowel obstructed just where it emptied into the cecum. Adhesions in the entire area were dissected away and a search made for the appendix but none was found. The lower end of the cecum seemed normal. The patient made a normal recovery and has had no trouble since.

In this case we know that the adhesions were the result of previous suppuration in the right lower quadrant. The resulting scar tissue finally closed off the small bowel. These postoperative obstructive cases ordinarily do well but it is important not to delay operation in the presence of an acute attack.

I believe that, where the patient's condition justifies it, it is good procedure to check for unnatural or unusual bowel adhesions at time of any operation in the lower right quadrant and to free such bands as may be found. Those patients who return after appendectomy and tell you that the operation did no good and in whom you can figure no definite pathology, are, I believe, cases in which the operation failed to release some of these obstructive bands.

Postoperative Paresis or Paralysis of the Bowel.—I turn now to consider this condition, which I regard as the most common serious postoperative abdominal complication. It occurs at times in individuals where there is neither excuse nor apparent cause for it. Simple abdominal surgery, with a minimum of handling of the bowel, may be followed by almost irreparable paresis, whereas a surgeon may check the viscera from one end to the other, perform an extensive operation and find the patient recovers without a gas pain.

The possible causes of accumulation of gas are: (1) excessive fermentation in bowel; (2) swallowed air; (3) arrested or modified intestinal peristalsis; (4) abdominal contraction; (5) relaxation of sphincters.

The distention from gas may become so great that a partial intestinal paresis may soon be converted into a total intestinal paralysis resulting in a distended inert tube. This may be further aggravated by mechanical obstruction occurring, in certain regions, through angulations due to its own overdistention.

No surgeon of any experience has failed to see this dreaded complication, and no surgeon who has seen it can fail to appreciate its serious possibilities. If there is any condition which calls for more patient, painstaking and prolonged effort on the part of the surgeon, I do not know what it is.

Until the last few years, the best weapon we

had to combat this complication was the colonic irrigation *properly carried out.* These last three words are important because the procedure requires anywhere from one-half to three hours, needs six to ten gallons of warm water and must be done patiently, gently, perseveringly, yet skillfully. The warm solution must play through the entire large gut persistently to help set up a normal peristalsis and often not till many gallons of water and much time has been consumed will the manipulator be rewarded by a gaseous return which spells success.

The above measure is as useful today as it ever was, but we now have a reliable ally in the Wangensteen nasal suction. When instituted early and run steadily over a period of many hours or days even, it can bring back normal function to a gut which otherwise would have remained completely paralyzed. I would recommend that both may well be used on any and every case which assumes serious proportions. The fact is that the surgeon might be better off if nasal suction was established as a routine procedure during the second and third day postoperatively in all extensive laparotomies. I confess that at present I am undecided whether forced feeding and plenty of agarmulsion will keep down gas formation and prevent distention in a large percentage of cases or whether on the other hand the liquid diet may better be used along with nasal suction. In some cases, results have indicated that whichever method was used was not the best. At the present time, we are attempting to use the forced feeding agarmulsion plan in routine cases. However, when our best judgment gives reason to expect impending trouble because of the serious nature of a particular case we use the liquid diet and commence nasal suction early. Each procedure is of definite value in properly selected cases.

In extreme cases, the combined nasal suction and colonic irrigation cannot return peristaltic action to the distended and paralyzed bowel. If paralysis persists for some time, the last resource is an enterostomy. I wish to report such a case.

A man, aged forty-eight, was admitted to the hospital May 19, 1934, a few minutes after being first seen by me at my home. He had been ill three days. Pain had been severe on the first day, let up a while on the second, and then returned even worse on the third day. His abdomen was very distended and rigid, his temperature 102, pulse 100, respiration twenty-four. He was operated upon at once and a gangrenous ruptured appendix with abscess of the tip was removed and tubes inserted without breaking down adhesions. The adjacent bowel was badly inflamed.

His recovery was stormy during the first six days. Enemas were very successful but little gas was obtained on nasal suction. Purulent drainage from the wound was considerable. The drainage tubes were removed on the seventh day and pus was pouring from the wound. Temperature and pulse had returned to normal. He began to become uncomfortable on the eighth postoperative day and on the ninth was much distended, vomited and his pulse rate was elevated. Nasal suction and enemas were both used with some success and both gave some relief. He was given two or more normal saline solutions with glucose intravenously each day to keep up his strength.

This routine was repeated for seven days and nights from the ninth to the sixteenth postoperative day without success. Then the abdomen was opened by a left rectus incision and a catheter was placed in a loop of the greatly distended jejunem.

We continued nasal suction and irrigations but now were able to drain out large amounts of liquid bowel content through the enterostomy opening. The battle continued until the twenty-first postoperative day, when fecal movement started per rectum, and on the twenty-second postoperative day suction was discontinued and the man took nourishment per os and held it. On the twenty-seventh postoperative day, we removed the enterostomy tube. Fecal drainage from the wound continued profusely, but on the thirty-fourth day, we strapped the wound with adhesive and the drainage lessened. He left the hospital on the forty-second day in good condition; the fecal fistula closed itself after he left the hospital. His recovery was rapid and he has had no abdominal trouble since.

This case is reported in order to demonstrate that no case should be regarded as too desperate. This man got to the cyanosis and death-rattle stage on different occasions. He was obviously about to die many times, but a dogged persistence for well over a month on the part of both surgeon and nurses was finally rewarded with success.

Let me repeat, therefore, that this type of abdominal complication is one which can today be handled successfully with the various mechanical measures at hand, but it requires the undivided attention of an interested and persistent surgeon who personally follows every symptom and treatment in detail.

Conclusions

I have attempted to bring out nothing spectacular or new, but merely to emphasize the importance of: (1) adequate preoperative examination and preparation; (2) postoperative vigilance, watching for symptoms of complications; (3) persistent treatment of all complications which may arise.

THE ETIOLOGY OF CHOREA*

CHARLES H. SCHRODER, M.D.
Duluth, Minnesota

SINCE we are to speak of Sydenham's chorea we should begin with Sydenham. His paper "On the Dance of St. Vitus" is really a very modest affair. Freely translated the opening paragraph would run about as follows:

"This is really a sort of convulsion. It affects boys and girls from the tenth year to puberty. It manifests itself with a lameness or weakness of one or the other leg so that the weaker member drags itself along behind in a semi-paralyzed manner. The hand of that side if applied to the breast or some other part is unable to remain in that same position even for a moment but is twisted around to another position by a convulsive movement—whichever way the weaker member is drawn. Before the cup can be placed to the mouth he exhibits a thousand gestures, circular in type; for he cannot move in a straight line to his mouth but his hand is turned aside by spasm and he twists it hither and yon until, at length, by mere chance placing the drink properly to his lips, he throws it suddenly into his mouth and eagerly drinks it,—accomplishing the act in such a way that all onlookers are moved to laughter."

The rest of the article is interesting, but I shall forego transcribing it. It is concerned mostly with therapy. Nowhere is there any suggestion of etiology unless we consider such, the reference to the age of the patients.

From the time of Bright, however, the close association of chorea with rheumatism was taken for granted. It is so taken today. Nevertheless Osler, in his masterly monograph on this subject, while not exactly challenging the assumption, showed that the connection was often difficult to demonstrate, stating that only 21 per cent in his series showed a close association. He did state, however, that there is no known disease which, at autopsy, shows such a large percentage of cardiac defects. Since that time there has been much discussion as to the relation of rheumatism and chorea.

Steiner stated that he could find only four cases of articular rheumatism in 252 cases of chorea. Coburn and Moore note that chorea frequently occurs without clinical or laboratory signs of rheumatic activity and that many patients develop no rheumatic stigmata even after repeated attacks of chorea. They state that the cases of so-called "pure chorea" will run from 30 to 50 per cent. Other writers express similar views.

Then, in 1935, J. R. Gerstley wrote a challenging paper in which he concluded that chorea should be looked upon not as a disease but as a syndrome developing in a child predisposed by heredity and constitution, after psychic exhaustion or infection. He draws attention to the importance of wretched home conditions, domestic crises and inadequate diets. He thinks that there is a distinct chorea temperament to be noted in certain intelligent, over-stimulated and markedly introverted children. He noted again the evident relation of the disease to puberty and suggests that the endocrine glands must be closely concerned. "Rheumatism is a concomitant, not a cause."

This is a pregnant sentence. Nevertheless, we shall ignore its implications for the present and ask ourselves what percentage of cases with chorea ultimately present clinical evidence of chronic valvular heart disease.

Pfaundler and Schlossman answer that ultimately one-half of all choreic cases will present such evidence. Abt says that 32 per cent of his cases showed "cardiac complications." Jones and Bland in their scholarly analysis of 482 cases of chorea state that with observation extending over an eight year period 54 per cent showed rheumatic heart disease. When rheumatism alone was present this percentage of endocarditis rose to 86 per cent and they make this striking statement: "Rheumatic heart disease is less likely to occur when chorea is part of the syndrome."

Of course, in the relatively few cases coming to autopsy, marked cardiac changes are uniformly found. I quoted Osler's striking statement in this connection. Fagge found cardiac disease in seventeen out of eighteen autopsies.

Now, practically all recent writers admit that there are cases of what we shall call "pure chorea." Jones and Bland place the percentage at 28 and say that in these cases, even over an eight year period, no frank evidence of rheumatic

*Read before St. Mary's Hospital Staff, Duluth, Minnesota, November 4, 1937.

fever could be found. However, Schwartz and Leader studied carefully seventy-five cases of pure chorea and observed them from one to twelve years. They state decisively that after seven or eight years one hundred per cent seemed to show cardiac involvement. They ask: Is it true of chorea, as of rheumatism, that the heart is always involved?

Of course, we are hampered by the fact that the etiological agent of rheumatism is still "sub judice." Only a few years ago Wilson made the statement that apparently identical organisms may be recovered from healthy children as well as from patients with rheumatism and related infections. It is also true that blood culture from typical clinical cases of rheumatism frequently may remain sterile. So we can hardly look to bacteriology to solve our problem.

As Swift has well pointed out, rheumatism, like tuberculosis, does not come on as a typical acute infection but often has a long latent period. Gerstley's remark then that chorea does not act like an acute infection would certainly not disprove its rheumatic origin.

As can readily be demonstrated, pathology, too, cannot solve the question. The Aschoff body, it is true, is pathognomonic of rheumatism as is the tubercle in tuberculosis or the gumma in syphilis. This peri-arteriolar inflammatory nodule has indeed been demonstrated by Poynton and Holmes and others, in the brains of patients dying with chorea, along with areas of encephalitis or with meningitis. The verruca on the valve is also indisputable as to origin. But over the cases that come to autopsy there is no dispute. If the patient with chorea dies he dies of rheumatism or its complications. The question still remains whether he can have chorea without rheumatism.

Now, we wish to put together a number of observations. Hassler and Moller show that heart disease not preceded by arthritis is more fatal than when so accompanied. It is likewise true that the gravest complications on the part of the heart occur in rheumatism that is not linked up with chorea. Likewise, the subcutaneous nodule, of bad omen, is much more common when chorea is out of the picture.

This can only mean that a higher degree of immunity or shall we say of allergy, using the word to define a reaction that restricts the virus to a narrow field, exists in some cases than in others. It makes one wonder whether the allergic phenomenon in the brain itself is not the true cause of the chorea. Edema of the tissues is a marked feature in rheumatism. This edema is fairly well controlled by the salicylates and hence their clinical value, despite their lack of influence on the underlying pathology. If there was any evidence that one part of the brain more than another was affected in chorea, it would not be far fetched to conceive of a local tissue response here, similar to the reaction we picture in the joints or heart wall.

Heubner states that the peculiar character of the choreic movement cannot be referred to the motor centers or tracts (anterior central convolution and pyramidal tracts). The intended movement in chorea is exaggerated. Flexion, extension, rotation, supination are all irregular in time, character and degree. Cobb has shown in electro-myographic studies that one characteristic thing is the inability to sustain effort. Both voluntary and involuntary contractions are weakened. This may be confined to one side—the so-called hemi-chorea. Now it has been demonstrated that a lesion of the corpus luysii (subthalamic body) may produce a hemi-chorea and, as stated dogmatically by Martin and Alcock, "there is very little evidence that focal damage to any structure in the brain other than the corpus luysii or its emergent fibres results in hemichorea." This, of course, is organic, persistent chorea. We might mention in passing that the body of Luys lies in the mid-brain just below the optic thalamus and just internal to the fibres of the pyramidal tract as they pass down from the internal capsule to the cerebral peduncle. To the medial side is the nucleus ruber. Below is the substantia nigra. The corpus receives its main body of fibres from the lenticular nucleus of the corpus striatum.

That the lenticular nucleus and the corpus of Luys may be of prime interest in connection with choreic symptoms is evident from the beautiful work of S. A. K. Wilson on the anatomy and physiology of the corpus striatum and on the rare disease known as chronic lenticular degeneration.

These papers are much too elaborate to quote extensively. Suffice it to say here that he demonstrates that the nucleus lentiformis is practically independent of the cortex. It connects with the subthalamic body and nucleus ruber to form

the so-called lenticulo-rubro-spinal tract. The function of this tract is to exert a steadying influence on the final common path (lower motor neuron) and to maintain the tone of skeletal muscle. In other words it has an inhibiting effect upon the cortico spinal or pyramidal tract and when this regulating function is in abeyance then appear involuntary movements, incoördinated movements and such symptoms as tremor and athetosis. The intended movement is exaggerated and incoördinate in time and degree, due to spasm and the attempt to anticipate spasm. And this is chorea.

In the disease known as chronic lenticular degeneration we have a toxic or infective factor acting selectively upon a basal nucleus. It is associated with marked liver pathology and certainly suggests the similar selective action that takes place in icterus gravis—the so-called "kern-icterus." In the disease first mentioned, classically described by Wilson, we have a selective action limited to the lenticular nucleus and corpus of Luys, and a wide train of symptoms embracing tremor, spasticity, dysarthria, dysphagia, paresis, et cetera.

It would seem to be reasonable to assume that the rheumatic virus also might exercise a selective action upon these nuclei and thus bring about this train of nervous symptoms that we have come to recognize as chorea. And if it be remembered that chorea occurs in those individuals presenting a high degree of resistance or allergic response, we might expect that localized edema would play a large part in the actual pathology. This might explain the rather dramatic response to certain lines of therapy, such as the injection of autogenous serum into the spinal canal or the induction of hyperpyrexia by diathermy or other means, or to such drugs as seem to have the power to induce a "reaction" accompanied by eosinophilia (sodium iodide, arsenic, nirvanol, foreign protein, et cetera).

This, of course, is mostly speculative and does not appear to include those cases unassociated with discernible infection—the cases of "pure chorea." It is possible of course that this is a misnomer and that the infection is there, although not clinically discoverable. It is really beside the point to refer to the sedimentation test as a distinguishing aid, because, admittedly, chorea only occurs in cases of low virulence. Possibly the test, after provocative therapy, might prove of value. Nevertheless, unless all clinical observation is to be discredited, chorea does occur on a non-infectious basis and we have to face the question as to how this can be. What sort of mechanism is at work here?

Now, first of all is it possible that chorea can be caused on a purely psychic basis? What is the meaning of the seeming importance of the family's social set-up in Gerstley's experience?

Malamud calls attention to the fact that both the extra-pyramidal tract and the autonomic nervous system exert a marked influence on motor function. Also is it true that the vegetative nervous system is closely associated with the psyche? We have to reckon with the shadowy subject of conditioned reflexes and with the fact that abnormal motions may replace inhibited instinctive expression.

It is certainly possible to comprehend the possibility that under the influence of tremendous fright or excitement, with rapid breakdown of glycogen in the hepatic cells and production of excess of epinephrine, there might be augmentation of all nervous reactions and old pathways of conditioned reflexes and imitation arcs might be reopened. But could the expression in chorea-like movement be so close to chorea on an infectious basis as to defy differentiation? One is brought face to face with the fact here that Beattie and his confreres have been able to show that stimulation of certain hypothalamic centers can cause a widespread flow of impulses over the sympathetic system. The inference is plain, therefore, that these centers can and do act as a central depot for sympathetic reception. Thus a patho-physiological disturbance conceivably could be induced, by a different mechanism, in those very centers that would be concerned in a purely infectious process. In this connection we should mention that Obelli and others have shown that there is sympathetic innervation in skeletal muscle and a purely peripheral irritation might explain the mild twitchings often designated as "pre-choreic."

But what is back of this? Practically speaking, chorea may be said to be a pre-puberty disease. In other words the glandular activity and increased endocrine output of puberty changes the background in some way so that the choreic phenomenon ceases. The true explanation of this fact would go a long way to clarify our problem. One can hardly proceed further than

to restate the close connection between the endocrines and the normal functioning of the autonomic nervous system.

But perhaps we can proceed a step further. Widenbauer has brought forth some convincing evidence that the missing link in this whole discussion is the Vitamin B complex. On the basis of some very interesting case histories closely studied clinically and in the laboratory, he concludes that the "chorea constitution" (Gerstley also speaks of a typical chorea type) depends upon a long deprivation of Vitamin B. The neuropathic child and the young gravid woman are in similar stages of deprivation. The B complex is preeminently concerned in muscle, nerve and joint nutrition. Rheumatism and the various affections associated with chorea flourish when the supply is low. The very incidence of chorea, with a new year maximum and summer-fall minimum suggests the relationship. The complications of furunculosis and other staphylococcic skin lesions provide further evidence. He also points out the calcium deficit in chorea and the relationship of tetany and parathyroid deficiency with B avitaminosis.

Recalling that prominent symptoms of beriberi are circulatory—to wit, enlargement of the heart, arrhythmia, exaggerated action, systolic murmur—this would seem to furnish an interesting parallel to those "mobile" heart symptoms that Trousseau called the distinguishing mark of rheumatism. That there is also a close parallelism of action between vitamin and hormone has often been suggested.

Nevertheless, this is not to get away from the whole question of infection. Beri-beri itself is more than an avitaminosis. The element of microbial action is by no means excluded. Matsumara and his colleagues claim that the principal etiologic element is a Gram-negative motile bacillus. However this may be, it does not seem possible in the present state of knowledge to make the dogmatic statement that chorea is dependent on an infectious process, or, on the other hand, that it is not related to infection.

The writer is not defending either view. His purpose is to arrange and digest the evidence.

MEDICAL BOOKS FOR THE LAITY

THOMAS E. KEYS, A.B., M.A.*
Rochester, Minnesota

MANY people are reading and will read on medical subjects. The important immediate concern is that this material be authentic, well written, and on a subject of medical importance. Certainly the publishing field bears witness to the popular demand for medical knowledge. A glance at the Index Catalogue of the Library of the Surgeon-General's office (the largest medical library in the world) shows that members of the staff of the library have cataloged at least 1,500 manuals of popular medicine, 400 more extensive books on the subject and more than 140 popular medical journals. Most of the journals are extinct. Even syphilis, which until recently was whispered about over the radio as "the social disease," has been given wide publicity to help in its prevention and ultimate cure. Recent authoritative treatises published in 1937 on this subject have included: S. W. Becker's "Ten Million Americans Have It" (Lippincott), Morris Fishbein's "Syphilis, The Next Great Plague to Go" (McKay) and Thomas Parran's "Shadow on the land, Syphilis" (Reynal and Hitchcock).

An important medium for information on popular medicine and hygiene are the health journals. Such is *Hygeia,* the authority and reputation of which is above reproach.

The American Medical Association and the National Health Council also publish pamphlets on many subjects in the field of health and preventive medicine. The Department of Health and the Department of Labor of the United States contribute similarly to popular education on problems connected with good health. These pamphlets are published at cost and are available to all persons.

In establishing a basis for the selection of popular medical books the following criteria were used: (1) that they be written in words understandable to the average layman with a simple vocabulary and in well written, pleasing style; (2) that they be written on good authority on

*Reference librarian, The Mayo Clinic, Rochester, Minnesota.

a subject of importance; (3) that they be published by a reputable house, and (4) that they do not attempt "cure-alls" or try to take the physician's place. The cure of disease we trust to our physicians and the progress of medical science bears witness that the ills of mankind are placed in safe hands.

For the rural communities there have always existed a few "family physicians" and home doctor books. One of the uses of these books, in days of poor transportation, was to suggest what to do before the doctor arrived. Today, they are worth while in cases of emergency. A recent book published on good authority is Dr. Morris Fishbein's "Modern Home Medical Advisor" (Doubleday, 1935). A book of the same type published primarily for social workers is Dr. R. C. Cabot's "Layman's Handbook of Medicine" (Houghton, 1937).

An interesting approach to the lay study of medicine lies in what may be termed "get acquainted books." These include books on medical history and biography. One of the most inspiriting books I have read is Gustav Eckstein's "Noguchi" (Harper, 1931). It not only introduces the reader to a remarkable personality but is a story of the fight against infectious diseases told in such a way that it is profitable to the laity.

Hans Zinsser has written in a vivid manner the story of typhus fever in his "Rats, Lice, and History" (McClelland, 1935).

One cannot go very far in getting acquainted with medicine before coming into contact with the works of Sir William Osler. His essays, "Aequanimitas, with Other Addresses to Medical Students, Nurses and Practitioners of Medicine" (Blakistons, 1920, ed. 2) inspire in the reader great respect for the medical sciences. This is a type of book that will appeal especially to a first year medical student. Similarly, the excerpts from his writings in "Counsels and Ideals" (Houghton, 1921, ed. 2) make good reading. Perhaps the best written history of medicine from the standpoint of the laity is Osler's "The Evolution of Modern Medicine" (Yale, 1921). To become acquainted with the man one should read his life, "The Great Physician" (Oxford, 1934) by Edith Giltings Reid. A more scholarly biography is H. W. Cushing's "The Life of Sir William Osler" (Clarendon Press, 1925, 2 v.).

Other important medical biographies or autobiographies include Vallery-Radot's "Life of Pasteur" (star edition), R. M. Wilson's "The Beloved Physician, Sir James MacKenzie" (Macmillan, 1926), Nathan C. Goodman's "Benjamin Rush" (University of Pennsylvania Press, 1934), Victor Heiser's "An American Doctor's Odyssey" (Norton, 1936).

In the field of medical history mention might also be made of Victor Robinson's "History of Medicine" (Froben reprint), H. W. Haggard's "The Lame, the Halt and the Blind" (Blue Ribbon, reprint, 1935) and Morris Fishbein's "Frontiers of Medicine" (Williams and Wilkins, 1933).

There is need for an authoritative popular book on human anatomy. Barnes and Noble have published an "Atlas of Human Anatomy" (1935) with colored illustrations by Franz Frohse and Max Brödel. This is good, but a more extensive book is needed.

In the field of physiology, the functional study of the human body, an excellent book is Dr. Logan Clendening's "The Human Body" (Knopf, ed. 3, 1937). Dr. Clendening included in his book, also, the body as it is related to disease and the development of medical science in the combat of disease. A recent book which promises to be of interest is A. J. Carlson's and Victor Johnson's "Machinery of the Body" (University of Chicago, 1937).

A large percentage of the patients who are being seen by physicians today are suffering from functional neuroses and chronic nervous exhaustion in general. Some of these patients, no doubt, have received from books not written for the laity information from which they have drawn faulty conclusions and they may have imagined their many ills. For the nervous patient himself, however, Dr. W. C. Alvarez has written his monograph, "Nervous Indigestion" (Hoeber, 1931). It makes enjoyable and profitable reading. Two books that deal with normal psychology are H. A. Overstreet's "About Ourselves" (Norton, 1927) and G. H. Dorsey's "Why We Behave Like Human Beings" (Blue Ribbon, reprint, 1930). Justification for neurotic personalities is expressed in L. E. Bisch's "Be Glad You're Neurotic" (McGraw-Hill, 1936). The history of insanity in America is well written in Albert Deutsch's "The Mentally Ill in America" (Doubleday-Doran, 1937). Books that share personal experiences in hospitals for the insane with the reader are the following: C. W. Beers' "A Mind that Found Itself" (Double-

day-Doran, reprint, 1932), M. M. Woodson's "Behind the Door of Delusion" (Macmillan, 1932) and W. B. Seabrook's "Asylum" (Harcourt, 1937). "Why Men Fail" (Century, 1928, edited by Morris Fishbein and W. A. White) is an analysis of the causes of failure, written for the average man or woman by the leading psychiatrists in the country. It also tells how failure may be turned into success.

An important bibliography on health books for the laity is that of Dr. Fishbein. This is published under the auspices of the American Library Association. A more up-to-date list may later be published by the Medical Library Association and also by the National Health Council. It is in this field that the intelligent layman must be directed if a national health program is to be realized.

It is through the efforts of both the laity and the medical profession that measures for preventive medicine and hygiene will be further adopted on a large scale. Authoritative books written for mature minds on this subject include the volume by W. E. Burkard and others: "Health and Human Welfare" (Ryerson Press, 1937), C. F. and N. W. Bolduan's "Public Health and Hygiene" (ed. 2, Saunders, 1936), and C. E. Turner's "Personal and Community Health" (ed. 4, Mosby, 1935).

While public hygiene deals with mass phenomena it is quite inseparable from personal hygiene. And it is important that the individual be schooled in how he can preserve his health and thus play his part in preventive medicine. C. W. Crampton's "The Boy's Book of Strength" (McGraw-Hill, 1936) is written especially for the adolescent interested in athletics and is an outstanding book. Logan Clendening's "Health Chats" (McKay, 1936); W. W. Bauer's "Health Questions Answered" (Bobbs, 1937); C. E. Turner's "Personal Hygiene" (Mosby, 1937); and L. E. Hawkin's "Health in Youth and Age" (Hillman-Curl, 1937) are among the newer books on this subject. M. J. Exner's "The Sexual Side of Marriage" (Norton, 1932) is a plain, frank, and practical book, and not poetically allusive like so many that have been written. The American Red Cross textbook on "First Aid" (revised edition, Blakiston's, 1937) is an excellent manual. It should be available in all homes in case of accident.

Books on diet should, I think, be recommended only on the advice of the physician. This should hold true for handbooks for patients suffering from such diseases as diabetes. In such diseases particularly, recovery depends on the intelligent coöperation of the patient. For patients suffering from arthritis, H. N. Margolis has written "Conquering Arthritis" (Macmillan, 1932).

To show up the quack and to help the laity to be on their guard against nostrums the American Medical Association has published "Nostrums and Quackery" (in three volumes, 1912-1936, volumes two and three edited by Arthur Cramp). Morris Fishbein has written "The Medical Follies" (Boni and Liveright, 1925) and "Fads and Quackery in Healing" (Blue Ribbon, 1935). An exposé of the drug racket is found in A. Rallet and F. J. Schlink's "One Hundred Million Guinea Pigs" (Vanguard Press, 1933). Of special interest to women is Mary Catherine Phillips' "Skin Deep; the Truth about Beauty Aids—Safe and Harmful" (Vanguard Press, 1934).

In conclusion, I might add that many books have not been included in this résumé. Some books have not met the requirements set up in the rules of selection, and of some books I have not had knowledge. If, however, I have suggested a few good books which may encourage others to read on a subject of vital importance and if I have shared with some of you my experiences in this field I shall have accomplished my aim.

LIVER EXTRACT IN GENERAL THERAPY

Case Report

J. J. HEIMARK, M.A., M.D.
Fairmont, Minnesota

FROM the time of my first impression of the efficacy of liver therapy in pernicious anemia, I have felt that it should be given a trial in other forms of debilitating diseases which were slow in recovery. Hence, during the several years in which liver has been on the market, I have used liver and liver extract in such cases. In using it on post-influenza cases routinely, I have felt that the therapy has shortened the period of exhaustion and general debility with which the patient has invariably contended for weeks and even months. Clinically, the same has held true for patients convalescing from pneumonia and empyema. I have also resorted to the use of liver extract in the treatment of those late winter and early spring patients from whom nothing tangible could be obtained except the histories of depletion and exhaustion so frequently attendant on long confining winters aggravated by minor ailments. It needed but trial to prove that liver extract had a decided restorative effect upon these patients far superior to that of other tonics and drugs.

It is an interesting thing to find that occasionally a case of essential hypertension will respond to liver. Again, others show no appreciable change. Since combining Rhodan with liver therapy in these cases, I have had more encouraging results than with any other form of treatment.

In piloting expectant mothers through to term with the usual pre-natal care I have found upon several occasions albumin in the urine and an increase in blood pressure towards the end of their pregnancies. After receiving 2 c.c. of liver extract two to three times a week for a couple of weeks, such patients have improved, their blood pressure has been lowered and the urine became albumin-free. I have considered these cases toxic types.

Recently I employed liver extract in the treatment of a patient with acute nephritis. Although to my knowledge it has not been recommended in the treatment of this disease, I am reporting the following cases with the suggestion that its use might merit further trial.

Case 1.—Mrs. J. H., aged thirty-nine, married and the mother of one child, consulted me February 23, 1936. She complained of headache, loss of appetite, swelling of the face, hands and legs. She had observed she was passing a decidedly small amount of urine during the day, and she stated that she had been getting progressively worse since she first noticed the onset of the trouble some one week previously. The scanty specimen of urine passed for examination revealed albumin 4 plus, casts and blood cells and cellular debris. The blood pressure was 178/118. There was marked edema of the entire body, especially of the extremities. I advised hospitalization, and upon refusal instructed that she be given complete bed rest and kept warm. Food was restricted to three glasses of skimmed milk or the same amount of home-made buttermilk per day—a Karell diet. Epsom salts were to be taken as needed. Before she left the office I gave her 2 c.c. of liver extract intramuscularly, and advised her to return in five days. On February 29, when she reported to the office I gave her the second injection of 2 c.c. of liver extract. The urine showed no improvement, but she stated that she had been passing more urine, that the headache was leaving her, and that she felt better generally. On March 7, she received her third 2 c.c. of liver extract. The urine showed a definite decrease of albumin. The edema was practically gone. She stated she was feeling greatly improved, and the headache had left her. On March 15, the fourth 2 c.c. of liver extract was given. The albumin was one plus and the edema was gone. She stated she felt so well at this time that she hoped she would not have to report at the office for further treatment. On March 24 she was given her fifth and final injection of 2 c.c. of liver extract. The urine was negative for albumin. She stated she felt "just fine," and she looked well.

I did not see this patient again until April 15, 1936. The urine then was normal. The blood pressure was normal. She looked as well as at any time in the period that I had known her, and she stated that she had not felt so well for several years. I have seen her occasionally since that time, and she has remained well. On March 6, 1937, I examined the urine again and it was normal. The last time, January 26, 1938, the urine again was normal.

Case 2.—The use of liver extract in a case of orthostatic albuminuria was followed by the disappearance of the albumin. A boy of seventeen was seen in July, 1936. The diagnosis of orthostatic albuminuria had been made two years previously and he had been told that the condition was of no significance and that he would outgrow it as time went by. He had learned to test his urine and was able to demonstrate albumin most of the time. It appeared to be more abundant when he was tired or following strenuous exertion. The boy had become introspective and apprehensive about his condition.

The boy was a well built young man with splendid physique, and the picture of health. The urine contained albumin plus two, on a basis of four. He was given empirically 2 c.c. of liver extract intramuscularly at five-day intervals for five doses. Following the first liver extract injection, the albumin disappeared from the urine and has not recurred.

Case 3.—In another case of a boy of fourteen the injection of liver extract seemed to be of benefit. The boy's father told me that the boy had not complained of anything in particular but that he had observed throughout the summer a lack of energy and a marked diminution in his ability for sustained work. His appetite was poor, his skin pasty and pale, and he had gained no weight during the summer.

Physical examination was essentially negative, except that the boy did not look well. His tonsils were greatly enlarged but only moderately inflamed. The urine showed a strong plus albumin. Following two injections of 2 c.c. of liver extract at five-day intervals the albumin disappeared, and following tonsillectomy the urine remained albumin-free.

After having experimented with liver and liver extract in general disease, I have come to the conclusion that the clinical results have been so intriguing that I was finally prompted to make this report. It would, indeed, be interesting to follow this work under a purely scientific setting so that a more complete report could be made. I firmly believe that the full measure of the possibilities of liver extract in the treatment of disease other than pernicious anemia has not yet been taken.

SURVEY OF PIONEER MEMBERS OF THE ST. LOUIS COUNTY MEDICAL SOCIETY

By RICHARD BARDON, M.D.

(Continued from April issue)

The Establishment of St. Luke's Hospital

The following article, written in 1921, was taken from the records of the hospital:

"In an old shack located on Third Ave. East, between Superior St. and the alley, St. Luke's Hospital opened for business. First steps for the organization of a hospital for Duluth were taken on October 18, 1882. One month later, the doors of the makeshift institution opened and members of the first board were hustling about to collect the $25, a month due for the structure. The town people being at that time more full of enthusiasm than cash, the first month's rent devolved upon the chairman of the board, Col. Charles H. Graves, and at the end of the first month's financial statement this contribution and a lone five dollar bill were all that glorified the treasury. For furnishings, the British Consul loaned the use of a range from the Government building, two beds had been begged from worthy citizens, as had one table, a few chairs and a blank book in which to register the rush of incoming patients. Mrs. Jessie Guion, an efficient matron, was engaged at $50 a month.

"At four o'clock on the afternoon of Nov. 18, a man on the Northern Pacific railroad broke his leg and by five o'clock the establishment of the hospital had been justified and has been ever since. This patient kept the hospital 'staff' busy for two months but added not a cent to the treasury until he was able to get back to work. A typhoid fever case caused temporary relief and excitement by paying $14 in advance only to have it efficiently counterbalanced by his remaining and requiring ten weeks care. One of the younger physicians, who had a very sick patient not long after, had him removed to the hospital, figuring that the man's death being only a matter of hours, an autopsy could be more conveniently performed with new equipment at hand. His plans went awry the following morning when he found his patient had recovered over night.

"It was a time of discouragement and stress to all concerned—a time when the water supply depended upon the strongest muscle and the largest pail; when the primitive means of sewage disposal and menace of typhoid necessitated most careful watching. Only the miraculous grit and determination of the board members carried this child of their brain to a sturdy maturity, though it was not long before 3,500 inhabitants of Duluth awoke to the needs the hospital was meeting and more and more opened their hearts and purses. Within two years the next step to a permanent building had been instituted and St. Luke's began climbing upward, this time to Second Avenue East and Fourth Street, where property had been purchased and a substantial building erected with a small indebtedness, some $1,700 being all that was assumed at that time.

"Rev. C. A. Cummings, the rector of St. Paul's Episcopal Church, was then the leading spirit in the organization of St. Luke's Hospital. He was aided by a board consisting of Col. Graves, G. V. I. Brown, Thomas B. Cullyford and Mrs. Ella B. Stone. The physicians of the town included Drs. Ritchie, Graff, Walbank, E. E. Collins, S. C. McCormick, C. F. McComb, George Davis and F. C. Sherwin.

"Upon the removal of the hospital to the new quarters on Second Avenue East, Mrs. Guion remained but a short time, to be followed by Miss Mary Scott as superintendent. The years following witnessed typhoid epidemics enough to try the staunchest heart and the new hospital was taxed far beyond its capacity and beyond the facilities it possessed to care for these patients.

"St. Luke's was also filling the rôle of a welfare institution, for at that time the Y.W.s and Y.M.s were not organized as they are now. The hospital seemed to be the center about which all charity and welfare work revolved and it was aided in many of these directions by the big-hearted men and women of the growing town who spent time, strength and energy to keep alive the sparks of helpfulness and assistance for those who blindly turned to this institution for help of all sorts. One father, mother and two children drove in forty miles to ask aid in locating an adventurous son who had set out unannounced to see the world. The hospital housed the parents and children for a week, while the means at hand were set in motion to find the young Columbus. Thanksgiving Day, 1884, according to the *Duluth Herald* of that date, found nineteen patients in the hospital enjoying a bounteous turkey dinner furnished by Thomas Cullyford, at that time proprietor of the St. Louis hotel. The account also notes but 'one female' amongst the patients, which at least was worthy of special mention.

"This hospital had one ward with fifteen beds, one private room, a sitting room on the second floor for the use of all patients and a small dispensary, used also for surgical emergencies. It was not many years before the limitations of the building were apparent and the present property at the corner of Ninth Avenue East and First Street was purchased. In 1900, the foundation was laid and on October 1, 1902, the present St. Luke's was opened, with a nominal capacity of seventy beds. The building cost in the neighborhood of $100,000, and at that time was considered one of the best equipped in this part of the country."

A later addition, greatly enlarging the hospital capacity, was opened in 1925.

St. Mary's Hospital

The following data concerning the organization of St. Mary's Hospital appeared in 1933, on the occasion of the forty-fifth anniversary of its foundation:

"In February, 1888, when Duluth was a pioneer city of a few thousand inhabitants, a small band of Sisters of St. Benedict—members of a religious community founded by St. Benedict for the purpose of caring for the sick and infirm —opened the City's second hospital in a small building at Twentieth avenue west and Third street." (Now St. Ann's Home.)

"Of that band, the last survivor, Sister Helen, died five years ago, but through the years younger members of the order took up the work and carried on under the direction of Mother Scholastica, the first president of the old St. Mary's Hospital Association.

"The first staff was composed of Mother Alexia Kerst and six other Sisters. The late Dr. W. H. Magie, one of the first members of the hospital staff, performed the first appendicitis operation at the hospital in 1891, and the first gastro-enterostomy operation in 1895.

"In those days, records still kept by the hospital disclose, patients came from miles around by carriage and sleigh. They were transported from floor to floor in a hand-operated pulley elevator, and their rooms and the wards were lighted by gas.

"In 1896, eight years after the first hospital was opened, the need for a larger building to accommodate the increasing number of patients resulted in the Benedictine Sisters purchasing the present hospital site at Fifth avenue east and Third street and constructing the first unit of the present hospital. In 1911, continued growth necessitated an additional wing having an increased bed capacity of sixty patients. In 1920, a new unit of six stories and a capacity almost equal to the then existing hospital building was added at a cost of $450,000.

"Other improvements included the out-patient department which was added in 1922; remodeling in 1924 to provide additional operating rooms, laboratory, supply room, an occupational therapy department, physical therapy department, a pediatrics department, x-ray offices, roentgenologist, orthopedic cast room and supply rooms.

"The hospital at present has a 290-bed capacity, forty Sisters on the administration and nursing staff, 104 student nurses, thirteen lay graduate nurses, three anesthetists, two physical therapists, an occupational therapist, a dietitian, eight laboratory technicians, and seven record room and office workers, eighty-eight

physicians on the regular staff, seventy-three on the visiting staff and eight resident internes."

In the introduction to the medical history of St. Louis County, mention is made of the hospital ticket system. The Sisters of St. Benedict began to issue hospital tickets in the fall of 1898, and discontinued their sale on July 1, 1913, when the Working Men's Compensation Act was passed by the State Legislature. The tickets were sold to laboring men and lumberjacks, a ward ticket costing $9 and a double room ticket $12. Physicians and surgeons received as compensation $2 per week for each patient under their care while hospitalized. The hospital ticket system was not only of great benefit to the lumberjacks and laboring men in general, but also helped to build up the hospital.

PIONEER PHYSICIANS OF THE VERMILION AND MISSABE RANGES OF MINNESOTA

By OWEN W. PARKER, M.D.

IN a recent history of Minnesota, it is stated that Minnesota has furnished much of the testimony from which scholars have traced the history of the earth's crust. Here and there are rocks laid down in the early periods of geologic time, which tell of the conditions which existed here long before there were eyes to see or hands to record them.

Thus the records of the Vermilion and Missabe Ranges, which came to the white man's attention only about eighty years ago, have yielded scraps of information which, pieced together with other scraps, give us much of the story of the earth during its remote past. For instance, inasmuch as only the lowest forms of algæ have left their fossil imprints in these ores, geologists have concluded that the great iron ore depository era must have been contemporaneous with the beginning of life on the earth. Also, other evidence left in the rocks proves that since these huge bodies of iron rust were laid down, Minnesota's area has been elevated and depressed repeatedly. This northern area of Minnesota is said to be the backbone of the continent. It had thrust its nose above the waters long before the Appalachian System or the Rocky Mountains were formed. These systems are only infants in geologic age compared to our own section.

In this great drama, it is interesting and inspiring to contemplate that it fell to the lot of our present pioneers to discover this great body of iron ore, after it had been deposited in the earth's crust untold ages before, and to turn it to the use of mankind.

In this work of the pioneers, we find that the pioneer doctors did their part equally well.

The discovery of iron ore on the Vermilion Range in the neighborhood of Tower brought settlers and a rush of miners to this vicinity in 1883 and 1884. The first load of iron ore from the State of Minnesota was shipped to Two Harbors from Tower in 1884, and was hauled by the Duluth and Iron Range Railroad. Mr. Thomas Owens was the engineer. He afterwards become superintendent of the road and is still living at Two Harbors, and is widely known in this section.

On July 31, 1934, the fiftieth anniversary of this event was celebrated by the Old Settlers and Pioneers of the Vermilion and Missabe Ranges. A monument commemorating this momentous occasion was unveiled at Soudan, where it stands near State Highway No. 1.

It had been known for a number of years that there was iron ore in this vicinity, but no active operations had ever begun before. George Stuntz, who settled on Minnesota Point in 1852, was one of the active explorers. He interested George Stone, who in turn interested Charlemagne Tower of Philadelphia. Charlemagne Tower organized the Minnesota Iron Company and started developments in the vicinity of Tower at the Soudan Location. Tower, of course, was named after him and became the mother city of all the Range towns. The mining location of Soudan was kept separate from the business location which was at Tower from the very beginning and has ever remained separate so that at no time has there been any business of any kind in the way of stores in Soudan.

This community had experienced a gold rush following the Civil War, gold having been discovered on Gold Island, in Lake Vermilion, and other places, and as a result of these various rushes and trips the Vermilion Trail had been established through the efforts of George Stuntz. A monument to the memory of this great pioneer stands at the entrance of Hibbing, in Stuntz township.

With the rush of early settlers to Tower for the mining of iron ore, there came Dr. Isaac van Dusen. As far as can be ascertained, he was the first doctor. He remained there for about one year. It is stated that he was a homeopath.

In 1885, it is said, Dr. John Alden came to Tower and remained there about five years, until 1890. He was in private practice. During 1887 there were exploration camps at Ely, and Dr. Alden used to visit these camps at Ely, often riding on horseback to them, a distance of twenty to twenty-five miles.

I am told by old timers that for a few months in the summer of 1887 Dr. Alden had an assistant, a Dr. Anderson, stationed at Ely. He was a young man about twenty-five years of age. A little later Dr. Joseph B. Noble came to Tower and remained there for a number of years.

The first doctors for the mining company at the Soudan Mine, so far as can be learned, were Drs. Robert and William Hutchinson, who came originally from Capron, Illinois. One of them has a son living there at the present time who is a doctor. These men were the first doctors to take care of any iron mining company medical practice in Minnesota.

The Minnesota Iron Company erected the Soudan Hospital in the spring and summer of 1889. This hospital was the first on any of the iron ranges in Minnesota. It stands on its original site and is still owned by the mining company, having passed on to the Oliver Iron Mining Company when the U. S. Steel Corporation was organized in 1901.

The first doctor to come to this new hospital for the mining company was Dr. W. E. Harwood, of Joliet, Illinois, who took charge on May 1, 1889, and remained there until October 1, 1897. His health failed and he was forced to stop practice for a time and left for the west, living for a time at Denver, Colorado. After his health improved, he returned to the Range, locating at Eveleth to take care of the Minnesota Iron Mining Company's work at the Fayal Mine. In 1900, he established the Fabiola Hospital, and had associated with him Dr. Fred Barrett and Dr. Charles Lenont. Dr. Harwood later, after a number of years at Eveleth, gave up the work to specialize in his practice, and located in his former home in Joliet, Illinois, remaining there until the outbreak of the World War, when he joined the English Medical Service. He contracted pneumonia and died while in service at one of the surgical stations at the front in 1915 or 1916.

Dr. Harwood's first mining practice experience was at Ishpeming, Michigan, where he was an assistant to Dr. Bigelow, along with Dr. Shipman. He was a man of studious habits, fine character, and very conscientious in his work, always trying to improve himself, even through his last years. When he finally left the

Range, a testimonial dinner was given him, attended by a large number of his friends.

Associated early with Dr. Harwood at the Soudan Hospital was Dr. Wm. W. Richardson, a graduate of the Northwestern Medical College, who interned in Cook County Hospital. He came originally from Princeton, Illinois. This town happened to be the home at one time of a brother of William Cullen Bryant, the poet.

After Dr. Harwood left the Soudan Hospital on account of his health, Dr. Richardson became head of the hospital and continued so from October 1, 1897, to October 1, 1901.

After leaving Soudan, Dr. Richardson went to Alabama as surgeon for the Tennessee Coal and Iron Company, remaining until about 1905, when he located at Los Angeles, California, becoming a prominent surgeon and specializing there in bone and joint surgery. While operating in May, 1924, he was suddenly seized with a heart pain which compelled him to stop the operation and immediately go to bed. He lived only a few days. At autopsy, his death was found to be due to coronary thrombosis. He was a very capable man in medicine, well trained, and an excellent surgeon. He read German and took German medical publications even while at Soudan as a young physician. He held a teaching position in one of the medical schools at Los Angeles, and was in the World War, stationed somewhere in Europe. He was a great admirer of Christian Fenger, having worked with Fenger in Cook County Hospital. It was the privilege of the writer to be associated with him during his first few months on the Range. Dr. Wm. de La Barre of Minneapolis was also associated for a number of years with Dr. Harwood and Dr. Richardson of Soudan.

Dr. Charles Goodrich Shipman was the first physician to locate in Ely, Minnesota. As previously stated, there had been exploration camps in Ely during 1887 and Dr. Alden of Tower at times made visits to these Ely camps, but there had been no permanent physician until Dr. Shipman came.

Charles Shipman was born August 27, 1856, at Madison, Wisconsin. His father was a veteran of the Civil War and was commonly spoken of as Colonel Shipman. Dr. Shipman attended the Wisconsin University at Madison three years. His family moved to Chicago in 1874, and there he attended the old Chicago University for one year. He graduated from Rush Medical College in 1881 and was president of his class. He took special work in surgery under Dr. Moses Gunn, and during his final year was Dr. Gunn's clinical assistant. He practiced medicine in Chicago for one and a half years when in 1882 he received an appointment as assistant to Dr. Bigelow, chief surgeon of the mining companies at Ishpeming, Michigan. He remained four years at Ishpeming, when in 1886 he was appointed chief surgeon for the mining company at Bessemer, Michigan, on the Gogebic Range. He built a hospital and remained there about two years, but, his health failing, he sold the hospital and spent some months recuperating in California. Later he was appointed Chief Surgeon for the mining company at Ely, Minnesota. He left for that district in May, 1888, and walked into Ely the last five miles, carrying such medical equipment and instruments as possible. Among these were dentist's forceps, as the mining physicians in those days before dentists arrived had to do extractions. For many years in the attic of the Shipman Hospital at Ely there were some old amptuation knives about a foot or more long that Dr. Shipman had carried with him on this occasion, and there still remain some of his old dental forceps.

The railroad was built into Ely from Tower and the first passenger train was run on July 4, 1888, but when Dr. Shipman came in May, 1888, a portion of the

track had sunk in a muskeg swamp about three miles out of Ely so that the track was impassable for trains.

Mrs. Shipman came on later in July, 1888. It took thirteen hours to make the trip from Duluth to Ely, Mrs. Shipman said, and the day coach left the track three times within the distance of 117 miles.

Dr. and Mrs. Shipman first had two rooms in Ely over a hardware store which was doing undertaking and there was a big sign, "Undertaking," in letters eighteen inches high. This was the source of many jokes at Dr. Shipman's expense. Before winter, Dr. Shipman had finished the building which was the first drug store in Ely, and which is still continued as a drug store. He lived in the store and had a front reception room and operating room and office.

During the spring of 1892 he started building the Shipman Hospital and finished it during 1893. When the panic of 1893 struck the whole country, it hit the iron ranges very hard, closing all mines. Someone said that during that year Dr. Shipman called the Shipman Hospital "Shipman's Monument"—it looked as though there would never be any use for it on the Range.

Dr. C. W. More of Eveleth, Minnesota, was Dr. Shipman's first assistant at Ely. Dr. More came to Minnesota in 1888, as assistant to Dr. S. C. Maxwell of Two Harbors, who had been appointed as physician to the employees of the Duluth and Iron Range Railroad Company at Two Harbors. About a year later, Dr. More accepted a position with Dr. Shipman at Ely and remained there over four years.

After Dr. More left Ely, Dr. H. E. Wunder came as assistant to Dr. Shipman, and remained until 1899. Later he was in charge of the Soudan Hospital, but left the Range about 1905, and now lives in Shakopee, Minnesota.

Of the many physicians associated at one time or another with Dr. Shipman, the pioneer physician, Dr. C. W. More, Dr. D. C. Rood, Dr. R. L. Burns,† Dr. George T. Ayres and the writer are still in this district—Duluth, Two Harbors and the Range.

Dr. Shipman left the Range in 1908 because of poor health. He went to Ocean Park, California, and for five years stopped the practice of medicine, then started in the practice of medicine again and practiced steadily five years until his death in 1918. He died suddenly in his own office, just after making a professional call on a patient.

Dr. Shipman was a man of magnetic personality, fine physique and handsome appearance. He was an excellent story teller and could tell innumerable stories in all the dialects, such as French, French-Canadian, Italian, Swedish, and especially the old Cornish miner dialects. He was an excellent entertainer and very hospitable, and was frequently visited by mining officials and other people of prominence who came through the Ely district. He was a sportsman and outdoor man, loved hunting, fishing, boating and baseball, having at one time been a player himself. He was also an excellent billiard player as well as an amateur boxer in his early life. He is still remembered by the old timers of the Range and is often spoken of in terms of affection and appreciation. He was an unusual character, and once one met him one never forgot him.

As a pioneer physician, he is entitled to great credit for the work he did in maintaining a high standard of medical practice on the Iron Range in the early days.

Dr. William H. Magie, one of the most prominent and able surgeons of Duluth and northern Minnesota, well remembered by all, built a small emergency hospital

†Since this was written, Dr. Burns has retired and gone to California to reside.

at Biwabik in 1892. Dr. Magie had been appointed surgeon of the Duluth, Missabe and Northern Railroad Company and for several of the mines operating in the Biwabik district.

The famous Merritt family of Duluth, Frank Hibbing and other explorers had done a great deal of work upon the Missabe Range, and it was commencing to open up at about this time. Dr. Magie placed in charge of the hospital Dr. Carroll Corson, who thus became the first physician to locate in Biwabik. In the same year, 1892, Dr. James R. Humphrey opened an office in Merritt, which was situated one mile east of Biwabik. He too was a surgeon for several of the mining companies operating in the district.

In 1893, the village of Merritt was almost destroyed by fire, and was never rebuilt. Dr. Humphrey moved his office to Biwabik where he built a small emergency hospital.

In 1894, Dr. Corson left Biwabik and Dr. Humphrey purchased the hospital owned by Dr. Magie. Dr. Humphrey operated the hospital and practiced in Biwabik until 1898, when he sold out to Dr. R. J. Sewall of Minneapolis. Dr. Sewall remained in Biwabik one year and removed to McKinley four miles west in 1899. Dr. Sewall sold the hospital in Biwabik to Dr. Charles W. Bray of Minneapolis, who moved to Biwabik in 1899. In 1906 the original building was destroyed by fire. A much larger hospital was built on the old site. This was operated by Dr. Bray, a greatly respected physician of Biwabik, until his death, July 8, 1937. Dr. Bray's wife, Mary B. Bray, is a graduate of the University of Minnesota Medical School, and assisted him very materially in the practice of medicine during their first few years in Biwabik. It is interesting to observe that of Dr. Bray's family of three sons and one daughter, all three sons are physicians, a truly medical family, and of the highest type.

Dr. H. L. Darms, with his wife, located at McKinley in 1892, very soon after the village had been organized. He served as mayor of the village in 1893. He left in 1894, going to Eveleth for Dr. More, who was sick. After this, McKinley was without a local physician until 1899, when Dr. R. J. Sewall moved there from Biwabik. In 1900 Dr. Sewall sold out to Dr. J. C. Farmer of White Bear, Minnesota, who practiced there until his death in 1921. Since that time, McKinley has had no resident physician.

The first doctor to settle in Virginia was Dr. James R. Humphrey, whom we have mentioned as having been early in Biwabik. This was in 1893. Dr. Humphrey was presumably in Virginia for only a short time, as he seems to have been in Biwabik until 1898. After him at Virginia came Dr. Stewart Bates, in 1893, and Dr. C. W. Miller. Dr. Bates built and operated the first hospital in Virginia.

Dr. Z. K. Brown came to Virginia in 1896 and died there from typhoid fever in 1899.

Dr. C. B. Eby was the first doctor to locate in Mountain Iron, about 1898. He was later associated with Dr. Avery and practiced in Virginia in 1901. He left the Range and later located in Spring Valley, Minnesota, where he lived until his death a few years ago. His death occurred while he was making a call to see a patient.

Surgical Relief of Adhesive Pericarditis

ADHESIONS between visceral and parietal layers of the pericardium may not be sufficient to cause symptoms. This condition is not infrequently first discovered at necropsy. When existing in conjunction with valvular heart disease, as is usually the case, thickened pericardium may aggravate the picture of valvular heart disease. When the pericarditis has been accompanied by extensive fibrosis of the parietal pericardium and has involved the surrounding structures of the mediastinum, the clinical picture may closely resemble cirrhosis of the liver, with enlargement of the liver, ascites with or without dependent edema. These three clinical types were nicely described in an analysis of fifty-five proven cases by George Douglass Head* of Minneapolis in 1905.

Many a case of adhesive pericarditis has been erroneously diagnosed cirrhosis of the liver and its diagnosis is not easy. The history of a heart pain in conjunction with an attack of rheumatic fever is very important. A large heart not sufficiently accounted for by the valvular lesions present, an enlarged liver and ascites with little or no dependent edema should arouse the suspicion that adhesive pericarditis is causing cardiac hypertrophy through adhesion to the chest wall, diaphragm and mediastinal structures or perhaps by scar tissue interference with venous return to the right auricle. A fixed heart, systolic retraction at the apex and Broadbent's sign are all of some value, but fluoroscopic examination of the heart revealing a tugging of the diaphragm or hilus shadows is more likely to be of diagnostic value.

The idea of the possibility of surgical relief in certain selected cases was first proposed at the turn of the century. Delorme's suggestion of decortication was first considered too radical. Brauer's proposal, made in 1902, of removing the ribs overlying the heart was more conservative and more often employed, but proved inadequate in most cases as it relieved only the tug on the anterior chest wall and did nothing to relieve the constricting effect on the heart in diastole or the interference with venous return to the heart. Sauerbruch, in 1913, resected a portion of fibrosed pericardium in one case with relief of symptoms. Since that time numerous cases have been reported in which thickened adherent pericardium has been stripped off the heart muscle and removed, the adhesions having been separated even as far back as the vena cava. The experimental and clinical work of Claude S. Beck have been outstanding in this country and he has reported numerous successful results.

The operation of cardiolysis following the suggestions of Delorme is, needless to say, highly technical. Avoidance of the pleural spaces, strip-

*Head, G. D.: Chronic adherent pericarditis. St. Paul Med. Jour., 7:251-259, 1905.

ping off of thickened pericardium without injuring heart muscles and vessels, the use of negative pressure and the avoidance of postoperative "pneumocardiac tamponade" must all be considered.

However, close cooperation between cardiologist and surgeon in the selection of cases does afford some hope for surgical relief for a certain number of these chronic invalids. While clinical cases in which symptoms are produced largely by pericardial fibrosis amenable to surgical treatment are not common, some are doubtless overlooked. Since the results of operation in certain carefully chosen cases are so remarkably good, the development of the complicated technic by a limited number of surgeons is highly desirable.

John Shaw Billings (1838-1913)

ON April 12, 1938, occurred the hundredth anniversary of the birth of a man whom Sigerist has properly designated as one who "truly ranks among the great pioneers of American medicine." The occasion was fittingly commemorated by a joint meeting of the Johns Hopkins Medical Society and the Johns Hopkins Medical History Club and the proceedings are set forth in the April issue of the *Bulletin of the Institute of the History of Medicine,* of the Johns Hopkins University, named the John Shaw Billings Memorial Number, covering 163 pages.

The life of this remarkable man in detail has been written by Fielding H. Garrison and was published in 1915. It is a classic and deserves to be read by all who are in any degree interested in the upbuilding of scientific medicine. It is the story of the accomplishments of a man who did more to strengthen and elevate his profession than has anyone else in its history.

To attempt to cover the same ground, even in condensed form, within the limits of an editorial, is manifestly impossible. Only the highlights can be mentioned.

Billings' career began simultaneously with the outbreak of the Civil War. At twenty-three he received his commission, served with great distinction throughout the conflict and remained in the army for nearly thirty-four years. This experience resulted in the initiation of four of his great accomplishments: he was responsible for the production of the monumental Medical and Surgical History of the War of the Rebellion; he developed the Army Medical Library, the Army Medical Museum and the Index Catalogue, all tremendous undertakings.

In 1876 he was approached by the Trustees of the Johns Hopkins Fund and induced to submit plans for the proposed Johns Hopkins Hospital, in competition with others. His plans were accepted and he was intrusted with the supervision of the construction, all, of course, with the consent of the army authorities. Notable as this service was, it was even less important than the part Billings played in the organization of the school and the selection of the personnel. The plans he proposed were radical to the point of being revolutionary at that time, but they were adopted, and the sanity of his ideas has been vindicated and proven by the subsequent developments. Seldom has so much responsibility rested on the shoulders of one man and never has it been more thoroughly justified.

He was called on to design other important hospitals, like Peter Bent Brigham, and made notable contributions to the literature of military medicine, the history of medicine, public hygiene, sanitary engineering and statistics. He was the author, according to Garrison, of "the most critical account of American medical literature (1876) and the best history of surgery that has been published in English (1895)." "He was," says the same authority, "a man of all-round ability . . . (who) did a giant's work for the advancement of American medicine."

Billings had a good heredity, but his people were poor and he secured his education at Miami with difficulty and personal privation. His training in the Medical College of Ohio was the usual two-year course of that period and he served an internship, an uncommon thing in to do in those days, in an obscure hospital. There must have been giant stature in his chromosomes, for he rose above these handicaps and left a heritage of almost unique accomplishment. Yet his name is scarcely known to the present generation. When Johns Hopkins is mentioned we think of Osler and Welch; the army suggests Beaumont, Sternberg, Reed and Gorgas; in medical history Sudhoff and Sigerist, all great and worthy men, but John Shaw Billings, quiet, self-effacing and competent, was the peer of them all, and without him

some of them would not have had their great opportunity.

He retired from the army in 1896 at the age of fifty-eight, having served for thirty-four years. His plan was to spend the rest of his days in Philadelphia doing research, writing and teaching in the University of Pennsylvania but the Fates ruled otherwise. The Public Library system in New York was in a state of flux, with three disconnected organizations serving the public as best they could. The services of a trained and capable coördinator were needed and Billings was the man. Reluctantly he gave up his long cherished plans, put on the harness for more public work, and in this harness he died in 1913. But he had done one more big thing in a quiet way; those "seventeen years . . . saw dreams realized in a way given only to those who deserve success." To him it was just the day's work.

G. C.

The College of Physicians and Medical Economics

THE program of the meeting of the American College of Physicians which was held in New York last month included at least two speeches which had nothing to do with scientific medicine. The presidential address by Dr. James H. Means took a slap at the attitude of the American Medical Association towards medical economic policies, and was widely heralded in the lay press as a revolt in the medical ranks of the country. The members of the College, to counteract any such impression, circulated a statement signed by 300 members, including President Means, denying that the College was in revolt against the organized medical profession. President Means' further remarks disparaging the importance of the present doctor-patient relationship suggest he has had little personal experience in the need of a doctor. His statement that "having a third party determine the size of, and even collect, the fee from the patient for the doctor is not only not an intrusion into the holy doctor-patient relationship but actually increases the likelihood of the patient's receiving from the doctor the best and wisest treatment the doctor is capable of giving" is hard to follow. If Dr. Means intends to convey the idea that collecting fees is distracting to the scientific practice of medicine, he is right. If, however, the majority of patients and practitioners prefer the present patient-doctor relationship to any other system so far offered, there is good reason to hold to our present system.

The other address by Dr. John P. Peters, professor of medicine at Yale University Medical School, was what one might expect from the secretary of the so-called "Committee of 430" doctors. The Committee having once declared itself in favor of more government influence in the practice of medicine, its secretary again makes a plea before the College for government subsidy for medical schools, hospitals and laboratories. He thinks the rich do not pay to support the institutions that care for the indigent, and yet enjoy medical advances developed through the instrumentality of the indigent. He infers the rich do not pay taxes and that the indigent are used as guinea pigs for experimentation. He makes a plea for government subsidy for the productive phases of medicine developed by educational and research institutes and hospitals and distrusts the vagaries of philanthropists. Government direction, in his opinion, could be no worse. It is our impression that most of the advances in our country in medicine, as in other fields, have in the past been accomplished by private enterprise. Any advances that have been made in the Yale Medical School were made possible by the large endowment of Yale University, which was accumulated largely from gifts from the wealthy. On the whole, the speech resembles some we have recently heard from Washington, which have sounded like an attempt to accentuate class antagonism. Perhaps the speaker belongs in Washington.

Proposals for changes in policies regarding medical practice, education and research should properly be initiated within the ranks of our national organization. Activities of societies of specialists should be limited to scientific discussion. Our organization is a representative one and it is wiser to leave the disposition of medical problems to our chosen representatives.

Correction

The widespread report that Professor Moritz Oppenheim was one of several medical men of Vienna who had committed suicide was repeated in an editorial entitled "Nazi Persecution in Vienna" which appeared in our columns last month. This was an error which we take pains to correct. Professor Oppenheim is still alive, a fact which will be welcomed by many professional friends in this country.

MEDICAL ECONOMICS

The State-Wide Survey

Has your county society started its survey of medical care and facilities in your own community? If not, the work should begin at once.

This survey, which means so much to the future of medicine in the United States, is being carried on in every county in the state. It is essentially a COUNTY SOCIETY SURVEY. Every member must do his part.

HAVE YOU DONE YOURS?

Study Under Way

Preliminary steps have now been taken for the state-wide survey of medical facilities by medical societies in Minnesota.

The first was an all-day meeting, Sunday, April 3, in Saint Paul, of the Committee on Medical Economics—chairman, W. F. Braasch, Rochester—where the following plans were formulated.

The Committee on Medical Economics, functioning through the Sub-Committee on Low Income and Indigent Problems, of which Dr. Coventry of Duluth is chairman, will have general supervision of the survey. It seemed best to group the county activities according to Councilor Districts, under the direct supervision of the respective councilors, who are familiar with the various local situations. In order to coordinate these state-wide activities the State Office of the Minnesota State Medical Association will assist county and district officers of the survey where it is needed and collect information required from state-wide health and welfare agencies.

It cannot be over-emphasized, however, that this survey is the individual problem of every county medical society, club, or district society in the State Medical Association. No one man or group can be held responsible for the success of this campaign. It must be a coöperative movement—a share the work plan.

Help in Fact Gathering

Both state-wide and local welfare agencies will be asked to assist in gathering facts for the study. They will also be asked for their candid opinion concerning the adequacy of medical care in each locality and what suggestions they may have, if any, on practical means to improve it.

Dentists, pharmacists, social welfare workers, nurses, hospital executives, health officers, all will be asked to contribute to this study to the end that it may be authentic, accurate and comprehensive—and to the end, also, that no one can attack it, when the work is done, on the ground of prejudice or insincerity.

Preliminary Meetings

Preparations are now going forward in nearly all councilor districts for preparatory meetings of physicians to insure interest, information and enthusiasm for the work. Such meetings have already been held in district three under the direction of Councilor B. J. Branton of Willmar, in district five under the direction of Councilor George A. Earl of Saint Paul, in district two under the sponsorship of Councilor L. L. Sogge of Windom, and in district eight under the direction of Councilor W. L. Burnap of Fergus Falls.

Conferences have been arranged with the Governor, with Mr. Herman Aufderheide, director of the State Relief Agency, Mr. C. R. Carlgren, chairman of the State Board of Control, Mr. W. R. Sassaman, executive secretary of the State Planning Board. Arrangements have been made also for a general conference with state officials of the welfare and professional organizations whose interests involve care of the sick.

Forms to be Filled

Eight forms have been provided for the survey by the Bureau of Medical Economics of the American Medical Association to be filled out under the direction of the county societies and by individual members. A ninth form, not yet ready, is to be used to summarize the information secured on the others in each county. Copies of this summary will go to the State Office and to Chicago; one will remain with the county society, club or committee in charge of fact-gathering. A tenth form is to be supplied to state organizations for securing information of a state-wide character.

Work to be Pushed

The survey is to get under way at the earliest possible date and county officers are urged by the chairman in charge to make it their most important job until the work is finished.

Following are important talks on the subject given at the Sunday meeting by Dr. R. G. Leland, director, Bureau of Medical Economics, American Medical Association, and Dr. R. E. Scammon of the University of Minnesota, president of the State Planning Board:

DR. LELAND

You have no doubt heard it said that the survey of medical facilities initiated recently by the American Medical Association represents a change of front on the part of the association. You have heard, perhaps, that, confronted with criticism, with threats of legislative action, and with a demand for action on the part of the U. S. Public Health Service, the American Medical Association has at last been forced to form a positive policy and take action.

Nothing could be farther from the truth.

Policy Unchanged

It was sixteen years ago when the American Medical Association first announced its policy on health insurance. At that time the association went on record as officially opposed to health insurance except and unless it was organized and sponsored by local county medical societies. It has never deviated in any respect from that policy; but in 1935 the House of Delegates of the national body drew up the now famous Ten Points which definitely set out the principles that should be followed in any system for distribution of medical care, including health insurance. Later the American Medical Association specifically encouraged the formation of local community plans of various sorts, where they were needed and where they were under medical society sponsorship, for better distribution of medical care to low income groups. Many such plans were started in various parts of the United States with the advice and the assistance of the Bureau of Medical Economics of the association.

No Response

In 1937 after rejection of the proposal brought to the House of Delegates at Atlantic City by the New York State Medical Society for federal subsidy for care of the indigent, a resolution offering to confer with any qualified government agency on new plans for medical care in the United States was passed. Up to December, 1937, no agency had made any effort to take advantage of this offer.

In December, 1937, the United States Public Health Service and representatives of the American Public Health Association did approach the Board of Trustees for a conference on the matter and the plan for a survey of medical care by the practicing physician in his county society was formulated.

New Method

The American Medical Association has always been deeply interested in the public welfare. The survey represents, merely, a new method for attacking the problem of public welfare, not a new interest in the problem of care for the sick. It represents, also, the first time that medical men have ever been asked to make a study of medical problems.

A Medical Problem

Our survey should be regarded as the first step toward adjustment of our system of medical care to the changes of our times. I should like you to regard it, also, in the light of a medical problem.

The first step in the study of a medical problem is the collection of data; the second is a diagnosis based on the data collected; and the third is a recommendation for treatment.

This survey will be effective only if we handle it according to these three steps and in the light of a strictly impartial medical analysis.

Not "Just Another Study"

It cannot be too strongly emphasized that this is not a study to be made and forgotten. We medical men must work with public agencies to make whatever changes are necessary to keep in step with the changes of the times. The survey will provide us with the facts we need in order to make those changes effective.

The American Medical Association has been much criticized because "it had no plan." We have always had a plan. Our plan has consisted of an effort to make hundreds of plans, if need be, to fit every local community because no plan on earth could be made to fit every section of the United States. The object of this survey is to fit our plans, if they are needed, to the needs of the local community.

Is Obstacle Economic?

There is a wide-spread belief that an obstacle exists between physician and patient. We must find out just how real and how extensive this obstacle is and what is its cause. Is the obstacle wholly economic? Is it rooted partly in ignorance and lack of special health education? These are questions we must answer and problems that we must try to solve.

The effort need not be costly to the individual county society. It may require time and sacrifice on the part of some of you; but I hope you will carry it through to the conclusion, no matter what it costs. We must keep in mind that the medical profession is under fire of much criticism; we must keep in mind, also, our own objective, which is and always has been, the best possible medical care for all the people.

DR. SCAMMON

It has seemed to me as I have listened to the outline of your plans that this survey is going to be exceedingly valuable. Indeed, I'm not sure that I shouldn't go further and say that this survey is essential.

In the first place, the survey is tied up with the medical profession. And it is the doctors and the doctors, alone, who are in a position to evaluate the character and nature of the services needed.

In other countries where attempts have been made to reorganize medical care, the task has been done without the assistance of the medical profession. The results were almost invariably unfortunate until, after a period of time, the medical profession was called in to help. We have many examples of this sort of planning from above—and without the doctors—for medical care.

Wasted Years

In England, health insurance was worked out from above in a period of three months. It took twenty-five years of modification to get that original scheme down to a workable plan. If the medical profession had been called in in the first place a quarter of a century of effort would not have been wasted.

In the second place, this survey and resultant plans are to operate by taking small areas as units and working out problems individually there.

Here in Minnesota we have 87 counties. Some are growing, some are declining in population; some are urban, some are rural; some are prosperous and some are not. We are not faced with a simple problem when we undertake to study and adjust medical care in Minnesota.

We Must Have Patterns

It is therefore extremely important in my estimation to go at this problem in the manner suggested by this study. We must get a pattern for each state and for each locality of the state; and this is the only way to get it.

On some of the blanks provided for this survey you will, of course, not get a perfect return. This fact should not constitute a cause for criticism. It is a fact that very few large surveys get a perfect return. Even insurance companies are unable to get them. It is possible on the basis of incomplete returns, however, to indicate "zones of confidence" in the returns. A process of cancelling out and evaluating will get at satisfactory answers in the end.

Choice: Data or Guessing

We never get anywhere at any constructive work without data. We must not expect that our results will be perfect; some variability is to be expected but this variability does not invalidate the usefulness of our attempt to collect facts.

The results of this survey may be merely a sampling. But we elect officers on a sampling process; not on the basis of a full vote. We have the choice of collecting data or of guessing. We can get the facts with a certain limit of error. And our best protection is certainly to work from information, even if it is not perfect, rather than from guessing. The public is best served where the medical profession takes the trouble to know where it stands.

DR. LELAND

Preliminary Preparations

The importance of preliminary organization for the survey cannot be over-estimated.

We must impress upon the individual medical man that this is "a medical analysis by medical men," that he, himself, is the only one who can push it through to a successful finish. We must not approach our task with a bias, either, or a preconceived notion that something must be done or that one plan or another is right or wrong, regardless. In some counties nothing needs to be done to improve distribution of medical care. We know that. But even in these counties we must have the information before we can safely come to such a conclusion.

By all means we should make use of findings of other organizations when we have reasonable assurance that the findings are accurate and honest.

For Accurate Sampling

I am very grateful to Doctor Scammon for his comments on the survey. Our findings will be samplings, only, as he told you. They will not be 100 per cent perfect nor will they lend themselves to mathematical statistical studies. But we must make an effort to have accurate sampling for all classes in a vertical rather than in horizonal lines. We must try to show the levels of service. Where osteopaths or chiropractors give a large amount of service, for instance, note should be made of the fact on the proper forms.

Community Project

We shall have failed seriously unless the confidence in the medical profession is in the crescendo as the study proceeds rather in the diminuendo in our communities. Our associates in the survey must be willing

to go along with us, not only in getting information but in carrying out the recommendations that result.

In Michigan the survey is already underway. The governor gave his blessing, appropriated $10,000 to it and plans to use the results for purposes of his own.

In Pennsylvania where the study is also advancing rapidly, the work has been parcelled out by districts to members of the Committee on Medical Economics.

However you plan the details of the work in Minnesota, you must not fail to ask yourselves when it is completed: has every man had his day in court? If he has not, suspicion of prejudice and suppression of fact will defeat the purpose of the survey and render the work of no avail.

Forms Ready

The forms for this study were printed by the American Medical Association and all but two or three are ready for use. Of these last, one is for pharmacists; and one for state medical societies to record information from state agencies and state-wide health services. Summary forms for the county societies still remain to be supplied. On these summary forms each county society will be asked to summarize the information secured on the other eight forms. The county society will then keep the original forms from which the summary is made and make three copies of the summary, one for the state association, one for the American Medical Association and one for the county society.

The returns on Form 1 (on volume of free and paid for service of each physician, etc.) are to be anonymous; but a key method of some sort will doubtless be needed particularly in the large societies so as to know how many have sent in their returns.

To Every Man His Chance

Publicity will have to be carefully controlled. The first announcement that the medical profession of the state is going to make a survey of medical care in each county will be news. A brief statement of the purpose of the profession in making the survey will suffice for this story. Publicity thereafter should be confined to state journals and special bulletins and talks to the profession until the survey is completed and we are ready to tell the public what we propose to do about it.

Whether to go to non-members for information is a question to be determined by each society. You must always remember, however, that when the survey is over everybody must have had his say. We must not leave the door open to criticism by anyone, even non-members. Give everybody his chance in this survey, be he friend or foe.

Medicine in Charge

The power of a medical organization which acts as a unit to preserve essential values of medicine and to serve the public interest is well demonstrated in two spots in America today.

One is in British Columbia where a Health Insurance Act was drawn up with the aid of physicians several years ago and was so emasculated in passage that the physicians flatly refused to function under it. As a result of that refusal there is health insurance in name only in British Columbia, pending the passage of a new act which will meet with the approval of the medical men.

Washington Controversy

Illustration Number Two is to be seen today in the District of Columbia where the Group Health Association plan for employees of the Home Owners Loan Corporation has become focal point for conflict and newspaper attack.

As noted before in these columns, the Home Owners Loan Corporation received a grant of $40,000 from the government to enable it to start this group sickness insurance plan for employees of the corporation. The Comptroller General of the United States subsequently ruled that the grant was illegal; the House Appropriations Committee indicated its disapproval.

Declared Illegal

The United States district attorney of the District of Columbia ruled that the association is unlawful under the Healing Arts Act of the District of Columbia which declares that it is unlawful for any corporation to practice medicine. The corporation counsel also ruled that the Group Health Association is operating in violation of the insurance laws of the District of Columbia.

With tacit Administration approval the association persisted in its organization and operation in spite of these rulings. Six physicians were hired to take care of the 6,000 members of the association.

The complete history of the opposition of the District of Columbia Medical Society as it was outlined by Congressman Shafer of Michigan and published in the *Congressional Record* of Tuesday, March 29, is as follows:

When the scheme was first broached, the medical society offered its coöperation in good faith to help provide the medical care. There was only one proviso: that the program to be worked out should not violate the legal, ethical and professional standards of the society.

Six for Six Thousand

It should be obvious to anyone that a plan whereby six physicians are hired to care for 6,000 people, the original grant for which was declared illegal by the Comptroller General and the plan of operation for which was also declared illegal both under the Healing Arts law and the insurance laws of the District of Columbia, could not comply with the standard set by the District of Columbia Medical Society.

The Society accordingly ruled that its members could not participate in the plan because it involved the illegal practice of medicine. And when one of them accepted employment from the Group Health Association and refused to resign his job, the Society dropped him from membership.

Hospitals are naturally bound by the same standards as the medical society and they were also unable to maintain professional relationships with physicians who were engaged in medical practice that violated the law.

Test Cases

The physician dropped from membership is reported to have threatened suit against the Society, of course; also a test case involving a Group Health Association member and physician and one of the hospitals inevitably developed. This case was seized upon and touted for all it could be made to yield as a weapon against the Society.

The episode was shouted in the newspapers and a member of Congress from California hastened to introduce a resolution into Congress for an investigation, not only of the District of Columbia Medical Society, but of all constituent societies of the American Medical Association and the national association itself.

Resident Vindicated

The truth of the hospital episode was this: An appendicitis patient was sent to the hospital for operation by one of the Group Health Association physicians. The patient was informed that her association physician was not permitted to practice in the hospital but that she might call any other physician or surgeon whom she chose. She refused and left the hospital to be operated upon, two days later, in another hospital, and by another physician. Her appendix, at the time of operation, showed that her condition was not acute. As the resident at the first hospital had originally declared, the case was not an emergency and he was not under obligation, therefore, to violate hospital rules to allow the operation.

The story told by the California congressman varied considerably from the facts and great capital was made of her dismissal from the hospital. In fact, it was noisily and erroneously reported that the appendix had ruptured after she left the first hospital and before operation.

Situation Precarious

As a result of the resolution and firmness of the Medical Society of the District of Columbia, the situation of the Group Health Association remains highly unsatisfactory and precarious. Only six physicians have so far been employed under it and these six physicians are not permitted to care for their patients in any reputable hospital in the District.

It is clear here, as in British Columbia, that the physicians themselves can control standards of medical care anywhere in the United States if they work together to maintain them.

In this connection it is important to make a note here of the fine address on the subject made in the House of Representatives by Congressman Shafer.

Champion in Congress

Said Mr. Schafer in the conclusion of a talk in which he reviewed the known facts of the Group Health Association controversy:

"In accusations of this kind (concerning the patient whose physician was refused permission to operate in the hospital) it is better to have the facts established immediately than to allow the medical profession to be exposed to loose charges. I have no doubt that an investigation would vindicate members of the District of Columbia Medical Society completely and for that reason I would support the resolution of the gentleman from California if it were not national in scope. . . . I am at all times ready to favor an investigation into charges against the medical profession or any of its reputable members because I believe that, except perhaps in isolated cases, such charges are idle gossip which would be disproved by an orderly investigation, and because I believe the medical profession is too important, its ideals are too fine, its service to humanity is too great and its necessity to human welfare too vital to allow it to be rendered suspect. I believe the members of the District of Columbia Medical Society whose conduct has been brought into question should be given full opportunity to establish in an orderly and convincing way the falsity of these charges."

Behind the Headlines

The American College of Physicians, a purely scientific association, was considerably startled, recently, to find its regular scientific meeting had been made the occasion for an entirely unsanctioned outburst of propaganda for the Committee of Physicians.

The first explosion was set off by Dr. John P. Peters of Yale, secretary of the now famous committee which released its proposals for Federal subsidy of medicine with considerable trumpeting in the lay press last November. Doctor Peters spoke before the College of Physicians at the personal invitation of Dr. James H. Means.

"Advantage of the Rich"

Said Doctor Peters:

"The practicing physicians offer solutions for health problems that overlook the production side (medical schools, hospitals and laboratories). Meanwhile the medically productive institutions are reduced more and more to philanthropy for their funds. . . .

"It is my impression that the government alone can assume the burden of providing, maintaining and correlating the necessary medical resources . . .

"It is rather amusing to reflect that, at the present time, most of the advances in medicine which the rich enjoy are developed in hospitals and institutions through the instrumentality of indigent patients. The fees which the rich pay, however, do not return to the support of those institutions but go to the practitioner who is exploiting new medical discoveries . . ."

Released in Advance

This interesting declaration received the sort of newspaper attention that such a paper always gets when it is given by a man who occupies a prominent place—and who hands his paper to the newspapers plenty of time in advance.

The second charge came from the retiring president, Dr. James H. Means of Harvard University, himself.

This time the American Medical Association was directly assailed as maintaining an attitude "close to standpatism."

"Like Jove on High Olympus"

"The behavior of the association is political," said Doctor Means. "It is partisan behavior; it champions a cause. At the present time the cause is something close to standpatism.

"But the policy can be changed at any time if the membership wills it. At the present time the membership of the American Medical Association is apathetic and inarticulate because it has no issues, no platforms set up to vote for.

"It is allowing the medical politicians to run things about as they please and official spokesmen, like Jove on high Olympus, hurl thunderbolts of wrath at all who differ in orthodox doctrine.

"As no democracy can be healthy without freedom of speech, real issues and an effective opposition party, it is desirable that those who believe in popular government bestir themselves to change this state of affairs."

Resentment Boiled

The effect of this well-timed challenge upon younger members of the College was electric, according to Minnesota representatives.

Resentment boiled up in all quarters. There was a general demand that the issue be thrashed out on the convention floor but wiser council prevailed.

Instead, a resolution was drawn up as follows and presented to the regents:

"Unfortunately an impression has been given to the press that the American College of Physicians is in revolt against organized medicine as represented by the American Medical Association.

"In asmuch as the College has never taken any action, and inasmuch as we have reason to believe that this reported impression does not represent the opinion of the majority of the members of the College, we, the undersigned Fellows of the College, respectfully request the Board of Regents to correct this impression publicly."

Means, Signer

In the midst of a busy session, 400 signers to this petition were secured in the space of two hours. One of them, ironically, was said to be Doctor Means, himself.

An answer from organized medicine was immediately forthcoming. Said Dr. Morris Fishbein in a Chicago address the next night:

"Doctor Means has never taken any actual part in the affairs of the American Medical Association and his ignorance of what is going on is actually lamentable.

"If he had any real knowledge of the present activities of the association which include a nation-wide inventory of medical needs and a determination of the means for satisfying them, he could not have spoken as he did . . .

"Dr. Means is, unfortunately, typical of a considerable number of physicians in laboratories or in full-time positions in medical schools who are unaware of medical practice outside of public hospitals or clinics.

Confiscatory Taxation is the Answer

"They have one chief objective . . . the securing of more and more government funds for the subsidizing of medical education, of hospitals and of the care of the sick.

"Their answer to the problem of medical care . . . is confiscatory taxation of industry and of the individual worker for the benefit of a bureaucracy."

To all of which Doctor Means issued the following meek statement in extenuation:

"I wish to correct a misunderstanding. It has been said that I am advocating a revolt against the American Medical Association. I am not advocating a revolt and nothing of the sort was mentioned in the speech which I made last night. What I did was to express the opinion that it would be wholesome if there should develop an enlightened opposition party within the democracy of the American Medical Association. This would be merely democracy functioning in a normal fashion."

Indignant Telegrams

It is reported, incidentally, that Doctor Means was promptly flooded with telegrams from all parts of the country—and that the prevailing tenor of these telegrams was indignation and a general demand for an explanation.

The real criticism of Doctor Means was not that he should hold opinions or that he should express them but rather that he should have expressed them when and where he did. The keenest resentment of all was expressed by College members who felt that they, a purely scientific body, had been placed in a false and unpleasant light before the country.

Silence Unfortunate

The whole episode gives rise to one obvious conclusion. The constituent state medical associations that make up the American Medical Association must hereafter vigorously express themselves on matters of economics, social welfare and the future of American medicine.

That the American Medical Association reflects the will of its constituent associations through their representatives in the House of Delegates is clear to anyone who is at all familiar with the sentiments and deliberations of this body. Under the Constitution the Board of Trustees must necessarily carry out the policies of the House of Delegates where such policies are clearly defined.

There is no doubt that a deliberate effort has been made by certain groups and agencies to promote a general impression that the American Medical Association does not truly represent organized medicine. These groups and agencies may be classified in a general way under the following headings: First, individual doctors who are not personally satisfied with the policies of the *Journal of the American Medical Association;* Second, politicians and others who want a complete change of method in the administration of medical care in the United States; Third, the patent medicine and proprietary medicine interests whose toes have been stepped on by the Council of Pharmacy and Chemistry; Fourth, the popular and ever growing number of throw-away medical publications supported by medical houses and exploiting uncensored medical advertising.

Knowledge—Judgment—Opinion

(Monthly Editorial Prepared by the Medical Advisory Committee)

Life to everyone is a contrast of emotions or thoughts.

To the child happiness, a smile, is easily changed into despair, a tear. The business man becomes a thinker in pessimistic or optimistic terms according to the stock market. The economists think in terms of supply and demand. They write volumes on their theories pro and con. The physician must make a diagnosis through scientific research before he can prescribe a treatment to cure or alleviate human suffering.

Your Medical Advisory Committee believes also that before a medical man endeavors to give an opinion about the results of others there are certain correlated facts that must be taken into consideration.

As a consultant or an expert he must have an extensive knowledge of the truths involved before he can pass sound judgment, which is the mental faculty of deciding correctly by the comparison of facts and ideas. His opinion then is worthy of consideration.

Too many of us in judging another man's work are inclined to do so hastily without study or reasoning. By giving erroneous opinions based on a lack of knowledge, and therefore faulty judgment, we start a large number of malpractice cases each year in Minnesota.

If without Knowledge, and hence lacking sound Judgment, we attempt to give correct Opinions and fail, the shame is ours and the results must be disastrous to the members of our profession.

Minnesota State Board of Medical Examiners

Self Styled Dutch Scientist Found Not Guilty by Duluth Jury

Re: State of Minnesota vs. Martin W. Pretorius.

Following a trial lasting three days in the District Court of St. Louis County, Martin W. Pretorius was found not guilty by a jury of eight women and four men. The defendant was charged, in an information filed by Thomas J. Naylor, County Attorney of St. Louis County, with practicing healing without a basic science certificate. The presiding judge was the Honorable Edwin J. Kenny.

Pretorius was arrested on July 14, 1937, at the Hotel Duluth where he was representing himself as an "Eminent South African Dutch Scientist—Hollywood Publisher—Newspaper Columnist and National Authority on Corrective Feeding and Body Culture." Pretorius represented himself as the founder and director of the Food Chemistry Educational Institute, Box 1857, Hollywood, California. Pretorius' method of operation was to give a number of free so-called health lectures during which people were solicited to take a so-called Martin Pretorius Home Study Course in Food Science and Rational Living. The cost of this course was represented as being $15.00. The pamphlet further stated that supplementary instructions would be given to "assist each student in solving their own health problem." * * * "Please indicate the conditions in which you and the immediate members of your family are particularly interested by placing an 'X' in the square provided." Then followed a list of eighty diseases and conditions including Bright's disease, cancer, epilepsy, tumors and tuberculosis.

According to the Clerk of the District Court of Atlantic City, New Jersey, one Martin W. Pretorious pleaded guilty on February 11, 1930, to practicing medicine without a license and was fined $200.00. Pretorius did not take the witness stand in his own defense, nor did he call any witnesses in his behalf. The defendant probably was aware that he would be questioned, in the event he took the witness stand, with respect to his educational qualifications, as well as his scientific attainments. It is interesting to note that when the State had completed the presentation of its evidence and a motion was made by the defendant for a dismissal of the charge on the grounds that "the evidence is insufficient to sustain the allegations of the complaint" and that "the facts proven are insufficient to constitute and show the commission of a public offense," the motion was denied after careful consideration by Judge Kenny. This shows that the Court was satisfied that the evidence was sufficient to sustain the allegations of the complaint and that the facts proven were sufficient to constitute and show the commission of a public offense.

The case was well tried for the State by Mr. Victor H. Johnson, Assistant County Attorney of St. Louis County. The defendant was represented by Mr. Jenswold of the law firm of Jenswold and Dahle.

Saint Paul Osteopath Removes Designation of "Aurist"

Re: Samuel M. Stern, D.O.

Following a complaint made to the Minnesota State Board of Medical Examiners that one Samuel M. Stern, a licensed osteopath with offices at 512 Hamm Building, Saint Paul, was using the designation of "Aurist" on his door and stationery, an investigation was made of the matter by the Medical Board. A careful study of the osteopathic law of this state and other authorities, convinced the Board that an osteopath is not entitled to use that designation in Minnesota. The Minnesota osteopathic law specifically provides: "The practice of osteopathy is hereby declared distinct from that of medicine or surgery * * *." The Minnesota law also provides that an osteopath cannot furnish medicine for internal use, nor can he do major surgery. The accepted meaning of aurist undoubtedly is a physician who specializes in the treatment of diseases of the ear without any limitation as to the scope of the treatment. It seems logically to follow that the term osteopathy by the very nature of its statutory limitations, cannot, and does not harmonize with the accepted version of the term aurist.

The Minnesota State Board of Medical Examiners so notified Stern and after consulting with his lawyers, Stern removed the designation.

Wright County Optometrist Pleads Guilty to Practicing Medicine Without a License

Re: State of Minnesota *vs.* Benjamin E. Nelson.

On April 25, 1938, Benjamin E. Nelson, who maintains an office to practice optometry at Buffalo, Minnesota, entered a plea of guilty to an information charging him with practicing medicine without a license. Nelson entered this plea of guilty before the Honorable Leonard Keyes, Judge of the District Court for Wright County. After a presentation of the facts by Mr. Thomas P. Welch, County Attorney, and Mr. Brist on behalf of the State Board of Medical Examiners, Judge Keyes sentenced Nelson to a term of one year in the Minneapolis Workhouse. The execution of this sentence was stayed and Nelson was ordered to pay the costs of the prosecution, to refrain from practicing medicine and to report to the State Board of Parole.

Nelson was arrested on March 8, 1938, following a complaint being filed against him by Mr. Brist, attorney for the State Board of Medical Examiners. The investigation conducted by the Medical Board disclosed that Nelson, despite a warning given him in 1935, was practicing medicine by prescribing diet, furnishing medicine to patients and examining specimens of urine. Prior to being warned in 1935, Nelson's method of operating was to give patients slips of paper which were to be taken to Beutner's Drug Store at Buffalo. These slips called for formula No. 1, No. 2, No. 3, et cetera. After he was warned, Nelson did his prescribing by word of mouth rather than in writing.

A most unusual incident occurred in the final disposition of the case, Nelson being represented by Mr. C. S. Hawker, a lawyer of Buffalo, who also was the Justice of the Peace who issued the warrant for Nelson's arrest, and before whom Nelson was arraigned. Mr. Hawker described Nelson as an outstanding citizen of Buffalo, while Nelson himself attributed his prosecution to the jealousy of the medical profession. It is a rather strange thing, but some persons who are prosecuted for practicing medicine without a license, never seem quite fully to understand that the question before the Court is their guilt or innocence, and that by entering a plea of guilty, the facts speak for themselves.

The State Board of Medical Examiners wishes to acknowledge the splendid coöperation of Mr. Welch, the County Attorney. Mr. Welch promptly instituted a prosecution when the evidence, consisting of numerous bottles of medicine and other exhibits, was presented to him.

Scientific Exhibitors

The gold medal of the Southern Minnesota Medical Association will be presented to the physician presenting the best exhibit of his work at the Minnesota State Medical Association meeting in Duluth.

This medal is presented annually as an encouragement to individual research by Minnesota medical men.

Dr. Donald Lowell Paulson of Rochester was married to Margaret Willius of Saint Paul, early in March.

* * *

Dr. C. E. Anderson of Brainerd has been elected chief of staff of St. Joseph's Hospital in Brainerd.

* * *

Dr. Henry Silver, formerly of Sebeka, has moved to Belview, where he will engage in the practice of medicine.

* * *

Dr. and Mrs. M. M. Hursh of Cohasset have returned from the south after enjoying a vacation of several months.

* * *

Dr. and Mrs. F. M. Manson of Worthington have returned from a southern trip which included a Caribbean cruise.

* * *

Dr. Jerome Scanlan of Minneapolis has moved to Pine City to become associated with Dr. A. K. Stratte in the practice of medicine.

* * *

Dr. Arden L. Abraham of Minneapolis has become associated with Drs. Gage Clement and J. R. McNutt of Duluth, in the practice of radiology.

* * *

Dr. S. W. Harrington of Rochester presided at the meeting of the American Association for Thoracic Surgery, which met in Atlanta, Georgia, early in April.

* * *

Dr. and Mrs. E. J. Kaufman, formerly of Appleton, have located in Anoka. Mrs. Kaufman is also a physician, and both will engage in the practice of medicine.

* * *

Dr. William Elliott, formerly of Newark, Illinois, has become associated with the Lenont-Peterson Clinic of Virginia. Dr. Elliott specializes in urology and skin diseases.

* * *

Dr. Carl D. Kolset, who has practiced medicine in Sanborn for the past thirteen years, has announced his retirement from active practice. His practice will be continued by Dr. R. J. Cairns.

Dr. L. E. Claydon of Red Wing has returned from a trip to South America. After spending three weeks on the Amazon he visited Peru, Ecuador, Colombia and Venezuela, taking moving pictures of various places of interest.

* * *

Dr. H. E. Michelson of Minneapolis addressed the Stutzman County Medical Society in Jamestown, North Dakota, at their annual meeting on March 31. A banquet was served before the meeting, and members from the surrounding societies attended.

* * *

The New York Academy of Medicine will hold its Eleventh Annual Graduate Fortnight October 24 to November 4, 1938. This year's session will be devoted to Diseases of the Blood and Blood Forming Organs. Those interested may write Dr. Mahlon Ashford, care of the Academy at 2 East 103rd Street, New York City.

* * *

Dr. A. E. Henslin of Le Roy, treasurer of the Mower County Society for more than fifteen years, was recently presented with a box of Nottingham cigars by the society members. Dr. Henslin has been incapacitated since January, due to a frost-bitten toe, but expects to have recovered in a few more weeks.

* * *

Dr. John L. McKelvey, at present a professor in the Peiping Union Medical College, China, has been appointed head of the department of obstetrics and gynecology at the University of Minnesota to take the position held for many years by Dr. Jennings C. Litzenberg, who will retire this spring. Dr. McKelvey was born in Kingston, Ontario, and is a graduate of Queens University.

* * *

The Board of Regents announces a gift of $10,000 from Mrs. John Dwan, the mother of Dr. Paul Dwan of the Department of Pediatrics, for the inauguration of a serum center at the University of Minnesota.

The Board of Regents also accepted a gift of $7,300 from the Citizens Aid Society of Minneapolis for the purchase of an additional Roentgen Therapy machine for the Cancer Institute.

* * *

Dr. R. M. Wilder of Rochester attended the meeting of the American Institute of Nutrition in Baltimore early in April, and conducted a round table discussion on diabetes at the meeting of the American College of Physicians in New York. He also addressed the meeting of the Postgraduate Assembly in Danville, Pa. Dr. Wilder will also attend the meeting of the Association of American Physicians in Atlantic City early in May, and will deliver the Mary Scott Newbold lecture before the College of Physicians in Philadelphia.

The Journal of Neurophysiology made its debut in January of this year. Its purpose is to concentrate in one periodical, experimental work on the functions of the nervous system, peripheral and central. Appearing bimonthly, contributions will be selected four weeks prior to publication, contributions not chosen to be returned to the author. This method will assure prompt publication of the important experimental work being done in this field. The editorial board consists of J. G. Dusser de Barenne and J. F. Fulton of Yale, and R. W. Gerard of Chicago. The publication is of particular interest to our readers in that Dr. Fulton, a former resident of Saint Paul, is a member of the editorial board. The publication doubtless fulfills a long present need and has our best wishes for its success.

* * *

Dr. Carl C. Chatterton last month was awarded the International Distinguished Service Medal for 1937 by the Cosmopolitan Club of Saint Paul. The medal is given each year to a resident of the city who during the past twelve months has rendered outstanding and unselfish civic service without remuneration. It is, of course, a recognition of Dr. Chatterton's services rendered crippled children at the Gillette State Hospital. For twenty-seven years he has been associated in this work and since Dr. Gillette's death has directed the policies of the State Hospital for Crippled Children. Dr. Chatterton has also shaped the policy for the Federal Social Security service in Minnesota in so far as it relates to crippled children and the set-up in this state is conceded to be the most efficient of any state.

* * *

Medical Department Reservists

The annual postgraduate course and clinical conference given by the Clinics in St. Louis for Reserves of the Medical Department of the United States Army will be held May 23 to 28, inclusive.

The regular enrollment fee of $10.00 is waived for Reserve Officers and the only expense will be a fee of $2.50 to cover the cost of the dinner honoring the Corps Area Commander and the cost of incidentals.

Appropriate military credits will be given for attendance.

* * *

Tenth Anniversary Medical Broadcast

Dr. William A. O'Brien gave his 520th weekly radio talk over WCCO, under the auspices of the Minnesota State Medical Association, Saturday, April 2.

The occasion marked a milestone in radio broadcasting in the Northwest, particularly in the use of radio for health education, and it was noted by a special tenth anniversary broadcast at the regular program hour on Saturday, April 2, by Dr. J. M. Hayes of Minneapolis, president, and Dr. R. M. Burns, of Saint Paul, chairman of the radio committee of the Association, and by Max Karl, director of education for station WCCO.

A luncheon followed at which Doctor O'Brien was guest of honor and to which leaders in medical and health education and in radio activities in Minnesota were invited. Among the speakers at this luncheon for which Doctor Burns acted as toastmaster were H. A. Bellows, station manager for WCCO at the time when the program began, Doctor Hayes, Dr. B. J. Branton of Willmar, R. R. Price, director of the extension division and chairman of the radio committee of the University of Minnesota, and many others.

Over the air and at the luncheon, physicians and experts in radio extended their congratulations to Doctor O'Brien and his sponsoring association and paid tribute to the unique radio gift of Doctor O'Brien which has enabled him to continue the program with continuously increasing popularity for this record period of years.

The Minnesota State Medical Association program, with Doctor O'Brien as speaker, was hailed as a model of its sort and acknowledged as one of the pioneers in educational broadcasting.

Radio officials pointed out, among other things, that Doctor O'Brien is accorded the unusual privilege of speaking only from notes rather than from a censored manuscript and that this faculty for talking spontaneously and directly to his listeners had much to do with his personal popularity as a speaker and teacher. Physicians pointed out that Doctor O'Brien, in all his years of regular broadcasting, had never veered from the standards of accuracy and medical ethics set for its public education program by the State Medical Association, that he had worked conscientiously with practicing physicians with whom his listeners discuss the broadcasts and that he had assisted materially in keeping medical men alert to new developments in practice.

The weekly program hour is now Saturday at 9:45 a. m.

Hospital Notes

Dr. C. I. Krantz of Duluth has been named chief of staff, and Dr. J. H. Peterson, secretary, of the Hearding Hospital, Duluth.

* * *

Minnesota Hospital Service Association

On the evening of April 18, the Minnesota Hospital Service Association held a dinner meeting to which were invited individuals from various Twin City activities to commemorate the occasion of the approval of the Association by the American Hospital Association. The Minnesota Association was one of thirty-eight throughout the country to receive this approval, and the only one in the state.

Mr. A. G. Stasel, Superintendent of Eitel Hospital in Minneapolis, and president of the Association, presided and paid tribute to the group of Saint Paulites who had the temerity and perseverance to initiate the Association, which began its activities in June, 1933, as the Saint Paul Hospital Association, and in 1935 adopted its present name when the Minneapolis hospitals joined. Today

(Continued on Page 351)

MEDICAL BROADCAST FOR MAY

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 9:45 o'clock every Saturday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

May 7—Sun and Air
May 14—Research and the Hospital
May 21—Periodic Health Examination
May 28—Protective Foods and the Teeth

MEDICAL SEMINAR ASSOCIATED HARVARD CLUBS

The Medical School Seminar at the 41st Annual Meeting of the Associated Harvard Clubs to be held at the Palmer House, Chicago, Illinois, on May 20, 21 and 22 next, promises to be an outstanding feature of the meeting. It will mark Dr. Burwell's first visit to Chicago in his official capacity as dean. The program is as follows:

The Harvard Medical School in 1938.....	Dr. C. Sidney Burwell, Dean and Research Professor of Clinical Medicine.
Trends in Pre-clinical Teaching	Dr. A. Baird Hastings, Hamilton Kuhn Professor of Biological Chemistry.
The Tutorial System in the Harvard Medical School.....	Dr. Walter Bauer, Associate Professor and Tutor in Medicine.
The Surgical Curriculum of Today.....	Dr. Elliott C. Cutler, Moseley Professor of Surgery.
Discussion by.....	Dr. Joseph T. Wearn, Professor and Head of the Dept. of Medicine, Western Reserve University, Cleveland, and Mr. Laird Bell, Chairman of the Educational Committee, Board of Trustees, University of Chicago.

The Seminar will begin about 2:30 p. m. on Saturday, May 21, immediately following a joint luncheon of all the schools beginning at 12:30 p. m., during which Frederick Roy Martin and William Allen White will speak briefly.

All graduates of the University are invited to attend. A limited number of admission cards are available for non-Harvard men who are particularly interested in medical education. These may be obtained by writing to Willard O. Thompson, M.D., Chairman of the Medical School Committee, 700 North Michigan Avenue, Chicago, Ill.

THE STATE MEETING

The 85th annual meeting of the Minnesota State Medical Association will be held in Duluth at the Hotel Duluth just before the Fourth of July holidays and therefore holds a special appeal this year, not only for those who are attracted by the distinguished scientific program but also for those who want to combine attendance at the meeting with a pleasant vacation in Northern Minnesota.

Unusual extra-meeting activities have been arranged for both the physicians and their wives so as to take full advantage of the place and time of meeting. One is the golf tournament to be held Saturday morning, July 2, following the close, Friday afternoon, of the scientific sessions. Another is the long boat trip on one of the big lake boats leaving the docks early in the morning and returning after luncheon in the afternoon.

The scientific session and exhibits, alike, are designed by the Committee on Scientific Assembly to be of value especially to the busy general practitioner. Emphasis is laid upon improved methods of treatment for conditions encountered in daily practice rather than upon the exceptional problems of medicine.

Among the interesting entries in the exhibit section is the prize-winning fracture exhibit of the Mayo Clinic, the exhibit on treatment of syphilis from the American Medical Association, the demonstration of pneumonia treatment by the Minnesota Department of Health and the demonstration of a simplified method of blood transfusion from the Department of Surgery of the University Medical School. In addition there will be daily lectures on diabetes at the exhibit and demonstration hours by the Committee on Diabetes and many other important exhibits by individuals and institutions, including an entire section devoted to scientific work of Duluth members and institutions.

Dr. Howard Haggard of Yale heads a distinguished list of guest speakers which includes Dr. Irvin Abell, president-elect of the American Medical Association; Dr. Roland Cron of Milwaukee; Dr. Hollis Potter of Chicago, who will give the annual Russell D. Carman lectureship; Dr. Edward Jackson of Denver; Dr. Philip Lewin of Chicago and Dr. Karl Meyer of Chicago; Dr. E. K. Marshall of Johns Hopkins and Dr. C. Anderson Aldrich of Winnetka, Ill.

For the medical economics section scheduled for Friday morning, July 1, from 11 a. m. to 12, the speakers will be Dr. J. M. Hayes, Minneapolis, president of the association, who will give his presidential address at that time; Chief Justice H. M. Gallagher of the Supreme Court of Minnesota and Mr. S. B. Houck of Minneapolis, representing the Minnesota Bar Association.

The first Herman M. Johnson memorial lecture will be given at a luncheon meeting to be held at the hotel Friday noon. Governor Elmer A. Benson, long a friend

of Dr. Johnson and well acquainted with his work, will be the lecturer.

Dr. Haggard will give the principal address at a public health meeting to be held Wednesday night at the Lyceum theater. The public will be invited to this meeting, which is sponsored jointly with the State Association and the St. Louis County Medical Society by the St. Louis County Public Health Association.

The annual banquet of the association will be held Thursday night at the hotel, with Dr. Haggard and Dr. Abell as speakers. It will be followed by dancing.

Round table luncheons arranged for Monday and Tuesday represent a departure in state meeting programs. The subject for the Monday luncheon will be social hygiene, and Dr. W. A. O'Brien will be the principal speaker and discussion leader.

All of the speakers at the Tuesday morning session will be invited to attend the Tuesday luncheon to answer questions and lead the informal discussion of the morning's program.

The annual meeting of the Women's Auxiliary will be held Thursday morning, to be followed by the annual luncheon at the Northland Country Club. The usual Board meeting will take place Wednesday at the hotel to be followed in the late afternoon by a tea at the Woman's Club.

AMERICAN ASSOCIATION OF INDUSTRIAL PHYSICIANS

Preventive medicine will be the keynote of the 23rd annual meeting of the American Association of Industrial Physicians and Surgeons which will be held concurrently with the Midwest Conference on Occupational Diseases at the Palmer House in Chicago, June 6, 7, 8 and 9, 1938.

Dr. Edward C. Holmblad, 28 E. Jackson Blvd., Chicago, Chairman of the Program Committee, announces the most interesting program in the history of this organization.

Advance programs of the meeting are available to any doctor interested and will be sent without charge to any practicing physician interested in attending this meeting. The sessions will be open to any practicing physician in accordance with the educational program of the Association to spread the propaganda of preventive medicine and absenteeism of employes.

For an advance copy of the program or for information on exhibits, address—Mr. A. G. Park, 540 No. Michigan Avenue, Chicago.

WASHINGTON COUNTY

The Washington County Medical Society met April 12. During dinner two representatives of the American Benefit Association spoke on the Association's hospital insurance policy.

The survey of medical care to be conducted by the American Medical Association in coöperation with county societies throughout the country was explained.

The meeting was then addressed by Dr. Carl Larsen of Saint Paul on the subject of "Sinus Disease" with special emphasis on surgical treatment.

In Memoriam

John T. Gill

1858-1938

DR. JOHN T. GILL of Echo, Minnesota, died suddenly on February 28, 1938, while making a call. He was eighty years of age.

John T. Gill was born February 26, 1858, at Monroeville, Ohio, where he grew to manhood. He attended Western Reserve College at Cleveland, and in 1886 received his medical degree from the New York Medical College.

After practicing in Monroeville for four years, Dr. Gill went to Kansas City, Missouri, where he practiced two years in the Cherry Street Hospital. He than practiced two years in Chicago, moving in 1895, to Echo, Minnesota, where he had practiced for forty-three years. The esteem in which he was held by his many patients and friends in the locality in which he practiced so long was well expressed in local newspapers. He never refused to respond to a call even in the early days when long trips over the prairie in winter necessitated the use of cutter or bob sled.

Dr. Gill was married October 9, 1895, to Blanche McClure at Redwood Falls. He is survived by his widow and seven children. He was a member of the Masonic order and had served on the village council and school board and as health officer.

Clarence Moors Golden

1877-1938

DR. Clarence M. Golden, of Tyler, Minnesota, passed away on March 23, 1938. He had been in poor health for the past two years and confined to his bed since August.

Dr. Golden was born at Marston, Michigan, June 30, 1877. After attending local schools he was a student for two years at the University of Michigan and received his medical degree from the St. Louis College of Medicine in St. Louis, Missouri, in 1906.

On November 6, 1905, Dr. Golden was married to Helen Grant of Bemidji. Her untimely death occurred in 1935. Dr. Golden was a member of the Lenont Hospital Staff in Virginia, Minnesota, for some eight years before removing to Ruthton in 1914. In 1920 he became affiliated with the Tyler Clinic and Hospital, which has been established by Dr. A. L. Vadheim.

Dr. Golden served as county coroner of Lincoln County for four years and had been active in Red Cross work, especially at the time of the World War. He was an able surgeon and conscientious in the care of his patients. He is survived by his son Harold and a sister, Mrs. Ruth Simpson, both of whom helped care for him during his last illness. He is also survived by a half sister, Mrs. D. G. Knapp, and his stepmother, Mrs. O. J. Golden, both of Kalamazoo, Michigan.

Clarence R. Morss

1880-1938

DR. CLARENCE R. MORSS of Zumbrota passed away at the Colonial Hospital, Rochester, Minnesota, on March 23, 1938.

He was born in Ledgedale, Pennsylvania, May 1, 1880, and accompanied his family to Scranton, Pennsylvania, in 1893. He attended school in Lackawanna and Scranton and in 1904 graduated from Lehigh College with a B.A. degree. He received his M.D. degree from the University of Pennsylvania in 1908, having been a member of the H. C. Wood Medical Society during his internship at the Philadelphia Methodist Hospital the following year.

Dr. Morss arrived at Coleraine, Minnesota, in April, 1910, to become attached to the staff of the Coleraine Hospital, a United States Steel Corporation institution. Resigning from this work in 1913, he practiced in Duluth until February, 1914, when he moved to Zumbrota, Minnesota, remaining there until April, 1917, when he returned to Coleraine. In May, 1918, he joined the medical corps of the army and was stationed at Camp Greenleaf and later at Fort Oglethorpe before spending ten months overseas, principally in France. Upon leaving military service in September, 1919, he relocated in Zumbrota, where he has continuously practiced.

Dr. Morss was prominent in social and civic affairs at Zumbrota. He had been president of the Zumbrota Golf Club, president of the Commercial Club and president of the Board of Health. He was a member of the St. Louis County Medical Society, Minnesota State and American Medical Associations. He was also a Knight of Pythias and a member of the Presbyterian church.

Homer Francis Peirson

1867-1938

MARCH 24, 1938, marked the passing of one of Austin's oldest physicians, at least in years of service. Doctor Peirson had practiced in the community of Austin since 1896, when he went there from Minneapolis upon completion of his internship.

Homer Francis Peirson was born Stepember 11, 1867, on a farm near Stewartville, Minnesota, where his parents came from Wisconsin in 1854. In 1874 his parents moved to Grand Meadow and there he attended school. He then spent one year at Carleton College, Northfield, Minnesota. In 1891, he graduated from the University of Minnesota. He took up the study of medicine at the Rush Medical College in Chicago, where he graduated. He then spent one year in intern work at St. Mary's Hospital in Minneapolis.

Doctor Peirson took little part in local politics, but served as coroner for a number of years and as president of the old Mower County Medical Society the year he came to Austin. He was a member of the state and national medical societies for a number of years. He was a member of a number of fraternal organizations, serving as medical examiner for them.

Doctor Peirson had but two real interests in life—his profession and his family. He leaves a widow and two daughters. He was always kind and considerate in his home, a devoted father, and friendly to all.

Although he had been in failing health the past two years he refused to give up his life's work, his practice of medicine. He went each day to his office and it was there he suffered the cerebral hemorrhage from which he died a few hours later.

Ira M. Roadman

1865-1938

DR. Ira M. Roadman of Minneapolis died in February following an emergency operation performed during a vacation trip to Mexico.

Born in Stahlstown, Pennsylvania, he was educated in Cedar Falls, Iowa, and at Cornell College, Iowa, receiving his medical degree from Minnesota.

For several years Dr. Roadman was chief medical attendant for the Duluth, Missabe and Northern Railway at Duluth. He later practiced at Onamia, Minnesota, and during the World War was stationed at Fort Leavenworth in the Medical Corps. In 1919 he entered the United States medical service for Indians and was stationed at Ponsford, Minnesota. In 1931 he retired and had since lived in Minneapolis.

Dr. Roadman was a thirty-third degree Scottish Rite Mason and a member of the Methodist Church. He is survived by his widow, a son, Howard R., and a daughter, Bernice.

HOSPITAL NOTES

(Continued from Page 348)

the Association numbers 163,000, including dependents, in its membership, being surpassed by only one similar association, that in New York City.

After listening to selections rendered by a quartet of nurses from the Deaconess Hospital of Minneapolis, Mayor Gehan of Saint Paul presented the certificate of approval to the president of the Association and paid tribute to the officers and trustees of the Association.

Mr. E. A. Van Steenwyk, executive secretary of the Association, presented some interesting figures in connection with the Association. Since the beginning of the Association's activities a total of about $750,000 has been paid out to hospitals for service rendered; about 400 members are now daily provided hospital care with an overhead cost last month of 11.1 per cent; every fifth person one meets on the streets of the Twin Cities is a member or dependent of the organization; 46 per cent of the members have their hospital bills paid entirely by the Association; an additional 44 per cent pay less than $10.00 for their stay in the hospital, and the remaining 10 per cent pay over $10.00.

In concluding the program, Dr. W. A. O'Brien talked on the service hospitals supply, and mentioned the high standing of hospitals in Minnesota.

PROCEEDINGS of the MINNESOTA ACADEMY of MEDICINE

Stated Meeting, Thursday, March 3, 1938

President, Dr. O. W. Yoerg, in the Chair.

PERFORATING HEMORRHAGIC (ENDOMETRIAL) OVARIAN CYSTS.*

Charles A. Hallberg, M.D.

In 1921 Sampson[7] published his first contribution dealing with a type of ovarian blood cyst heretofore variously designated as tarry, chocolate, perforating and hemorrhagic cyst. The term "ovarian cysts of endometrial origin" was suggested to distinguish this type of cyst from other ovarian hematomas.

As a result of the above and succeeding contributions by Sampson[8] dealing with this subject, the disorder was quickly accepted as a clinical and pathological entity and is now commonly designated as endometriosis or endometrioma of the ovary.

Endometrium within the ovary was first described by Russel[6] in 1899, which he believed represented an inclusion of the Müllerian duct. Pick[5] in 1905, in a notable study of ovarian hematomata, gave the first description of a typical chocolate cyst, and, furthermore, described the functional as well as morphological resemblance of the epithelial lining of the cyst wall to endometrium.

The following quotation of his paper is from the translation by Graves[1]:

> "As a result of the glandular development of the germinal epithelium, its invasion of the ovarian substance and the round cell proliferation of the surrounding stroma, there occurs in the ovary a form of adenoma which reflects a perfect likeness to the endometrium of the corpus uteri—adenoma ovarii endometroides; this tumor is especially likely to be associated with fibroids of the uterus.
>
> "The ovary is in such cases either insignificant (pure adenoma) or cystic (cystadenoma) and may reach the size of a goose egg. The single or multiple cysts are distinguished by a syrupy chocolate colored or more reddish content; and a more or less pigmented mucus-like membrane of the type of endometrium of the corpus uteri. The pigment of the contents and the 'mucosa' is derived from hemorrhages which follow the participation of the endometrial-like tissue in the menstrual and other congestions of the internal genital organs."

The prevalent theories of origin of endometrial cysts of the ovary may be divided into two groups: (1) the serosal theory and (2) the implantation theory.

The serosal theory owes its development mainly to Robert Meyer.[3] He points out that the pelvic peritoneum has its origin in the cœlomic mesothelium. He demonstrated that stimulation or injury of the pelvic peritoneum by means of inflammation may produce, during the processes of healing, a metaplasia of serosal cells enabling them to develop endometrial-like glandular structures.

This theory may be applied to the germinal epithelium on the surface of the ovary. Pick, as noted in the above quotation, ascribed the endometrial structure within the ovary to metaplasia and invasion of the germinal epithelium.

Novak[4] suggests that disturbances in endocrine function may serve as a stimulant to the formation of aberrant endometrium.

Sampson's implantation theory arises from the observation of blood flowing from the fallopian tubes during a pelvic operation performed either immediately following a curettement of the uterus or, more commonly, at the time of menstruation. He proved that blood thus regurgitated through the fallopian tubes carried with it fragments of uterine or tubal mucosa. These fragments of endometrium, falling upon the ovary, possess the ability to invade its surface and, with continued growth, develop into glandular or adenomatous structures. The adenomata thus formed react to menstruation in a manner similar to that of the uterine mucosa. The accumulated and retained menstrual blood results in the formation of blood cysts.

On the surface of the ovary, these hematomata appear as single or multiple minute purple cysts. Deeper penetration into the ovary results in the formation of cysts varying in size, filled with menstrual blood. As the cysts gradually enlarge with each menstrual cycle, rupture eventually occurs, spilling the contents of the cyst into the pelvis. The escape of fragments of aberrant endometrium may result in the formation of new implants upon the various pelvic structures. Dense adhesions are formed between the site of perforation and adjacent pelvic structures.

King[2] believes that so-called endometrial cysts develop from structures within the ovary. He describes numerous instances of tarry corpus luteum cysts and tarry cysts of the atretic follicle identical in gross and histological structure with endometrial cysts. The origin of the epithelial lining of the cyst wall is not established but he states it arises probably by metaplasia from cells which are present in the ovary.

Pathology.—The diameter of endometrial cysts usually varies from 2 to 6 cm. They may be single or multiple. When multiple cysts exist, they frequently communicate with each other, suggesting the occurrence of rupture of the wall into neighboring cysts.

The outer surface of the cyst is bluish gray in color and usually presents a wrinkled appearance. There are two striking and characteristic features of the appearance of these cysts after their removal, namely the presence of one or more perforations of the cyst wall, with a thick roughened area of ovarian tissue around it, indicating the site of dense adhesions; the second, the exceptionally thick walls of the cyst which stand apart and do not collapse after the contents have escaped.

The lining of the cyst cavity is usually stained a deep brown, from the retained blood. The contents of the cyst resemble thick chocolate syrup.

*Inaugural thesis.

The diagnostic feature of endometrial cysts is the discovery of an epithelial lining. Sampson describes the epithelium as being low cuboidal or columnar resting on a vascular stroma, sometimes containing gland-like structures resembling uterine glands. The stroma shows evidence of recent or of old hemorrhage.

The extent of the epithelial lining is variable. It may be found only at the site of perforation; it may line the entire cyst or a part of it; or may occasionally be entirely absent.

According to Sampson's investigations, the epithelial lining may be more or less completely cast off in certain phases of its reaction to menstruation. As regeneration of the epithelial lining occurs, it may exist only in limited areas.

Portions of the cyst not lined by epithelium consist of ovarian stroma and usually some areas of luteal membrane.

The routine pathological examination in the hospital laboratory fails to discover epithelial structures in the majority of instances, and as luteal cells are commonly encountered, the pathological diagnosis is usually corpus luteum cyst. It, however, seems probable that if studies were made of the entire lining of the cyst, discovery of adenomatous structures would be materially increased.

Endothelial cysts are infrequent before the age of thirty and rare before the twenty-fifth year. Approximately 10 per cent occur in the second decade. Their number is about 25 per cent greater in the fourth decade than in the third. If pregnancy has occurred, it is commonly limited to a single instance.

Its incidence among single and married women is about equal. A history of a previous pelvic infection is notably infrequent.

The almost universal existence of dense adhesions to neighboring structures makes for a varied and extensive symptomatology. Additional complexities in diagnosis may be provided by associated endometrial implants disturbing the function of the urinary and intestinal tracts.

The leading symptom is pain, in the form of dysmenorrhea of the acquired type. Pelvic pain may be present or absent throughout the menstrual interval, but in any event it is almost certain to be increased a few days prior to and during the menstrual period. It is usually described as an aching in the lower abdomen and frequently as backache in the sacral region.

Some form of disturbance of the menstrual flow is the rule, usually causing prolonged or increased flow, or both. This group of symptoms are quite identical with those met with in a case of subacute or chronic pelvic infection.

The information obtained by pelvic examination is frequently misleading. The usual characteristic features of an ovarian cyst, namely, a rounded elastic tumor, movable and readily identified as being separate from the uterus, are physical signs entirely foreign to a typical adherent hemorrhagic cyst. Instead, one finds a mass of indefinite outline, almost invariably with more or less fixation, in most instances intimately attached to the uterus, often nodular in the lowermost portions and usually sensitive to pressure. They may particularly resemble uterine fibroids occurring near or in the cervix.

Not infrequently, a relatively small cyst with numerous perforations and extensive attachments to the uterus, broad ligament, small intestine, sigmoid and omentum will produce a mass filling one-half of the pelvis.

Surgical procedures in this disorder are necessarily governed by the age of the patient, the extent of involvement of the ovaries, the condition of the uterus, and the existence of endometrial implants in other organs. If the disorder is localized in one ovary, and implants elsewhere are absent, removal of the involved ovary has usually proved to be sufficient. With extensive bilateral involvement, removal of both ovaries, with or without hysterectomy, generally is indicated. In young women, excision of the cysts may be tried, though reports indicate that recurrence is likely.

MEDIAN NERVE SUTURE, NEUROLYSIS OF ULNAR NERVE, PLASTIC REPAIR AND RESECTION OF ULNA FOR DEFORMITY OF HAND

Arthur F. Bratrud, M.D.

This patient, Miss S. S., at present twenty-two years of age, was first seen in August, 1926. She gave the following history at that time. While living in Madagascar she accidentally fell out of a tree, landing on the right hand with the hand partially adducted and the hand flexed. This occurred about January 5, 1925. She received a compound fracture of the wrist, with one of the bones sticking out through the broken skin. She was attended by a physician on the island, who applied a cast after reduction of the fracture. An infection resulted and the cast was removed. This was followed by extension around the wrist by means of a bandage. This bandage cut into the skin and an infection resulted in the sides of the wrist as well as lower end of the forearm and wrist. She was up and out of bed by the first of February, 1925. The wounds were not entirely healed until August, 1925. Later she received massage treatments, during the time that she was in Madagascar. She stated that she could bend the hand at the wrist slightly, but had no motion in the fingers in any direction. She complained at that time that she had no feeling in the radial side of the palm of the hand or on the flexor surface of the thumb, first and second fingers, and very slight sensation on the ulnar side of the palm of the hand, and flexor side of the third and fourth fingers, as well as the corresponding area on the back of the hand. She also stated there was complete numbness on

the back of the thumb, first and second fingers, and that she could turn the hand but very little.

When examined there was a dense, thick, heavy scar, about two and one-half inches in length, covering the entire flexor surface of the wrist and the lower part of the forearm. This seemed to be fixed to the bone. Pronation and supination at the wrist was very nearly nil. Fingers were held slightly separated, with no semblance of adduction, abduction, extension, or flexion. The hand was held in a position of abduction with the ulna pressing out into the skin and shoving the hand into that position. There was present very slight flexion and extension and slight abduction and adduction at the wrist.

This case presented a very poor outlook as far as ultimate good result was concerned. However, on August 23, 1926, she was operated upon at Fairview Hospital, at which time the following findings were present. There was complete severance of the median nerve at the wrist and a large amount of scar tissue around the ulnar nerve at this location. There was a mass of scar tissue between the profundus and sublimis digitorum muscles, and the ends of the tendons at the wrist. It appeared as though there were no tendons passing through this scar tissue. The mass of scar tissue, anterior to the radius, ulna and pronator quadratus muscle was completely dissected away. The median nerve was resected to a point when the fasciculi appeared normal. On account of the amount of the destruction of the median nerve it was extremely difficult to obtain apposition of the severed ends. A neurolysis of the ulnar nerve was performed. The hand had to be put up in an extreme degree of flexion in order to secure apposition of the severed ends of the median nerve, even after loosening this up into the middle third of the forearm. A predicle fat flap from the chest wall was then attached, splitting the fat fascia and replacing a layer between the scar tissue and the bones of the forearm, pronator quadratus and carpal bones. This left a good layer of fat anterior and posterior to the nerve and scar tissue. The pedicle flap wound was dressed with a parowax dressing as follows: Open sterile gauze is dipped in warm melted sterile parowax, and applied at once, before the parowax hardens to the skin and raw surfaces. This does not have to be removed before separation of the flap, and allows painless dressing. On September 7th, a separation of the pedicle flap from the chest to the right forearm was performed. A plastic closure of the raw areas of the chest was performed at this time. The flap was in very good condition. On January 5, 1927, a resection of the lower end of the ulna above the epiphysis was performed about one inch above the lower end of the bone, so as to allow the wrist to assume a normal position. In July, 1927, there was beginning return of sensation in the median nerve distribution of the hand.

This girl was advised to try to use the hand as much as possible, and to keep up massage as much as possible. Several years later a letter was received from her, stating that her hand was improving so much that she could bend and separate the fingers, and was beginning to play the piano. She was not seen again until December, 1937, at which time the following findings were present. There had been complete loss of growth of the radius on account of the destruction of the epiphysis which had resulted at the time of the original injury. This was present when first seen in 1926. The ulna had continued growth again after resection and was protruding downward so as to throw the wrist into the position of marked abduction. There was very slight pronation and supination present at the wrist. Flexion and extension at the wrist was present to a moderate degree. Abduction and adduction of the fingers was present and the fingers could be flexed, but not sufficient to close the hand completely. Intrinsic muscular action of the hand had returned completely. There was complete return of sensation in both the median and ulnar nerve distribution. The pedicle flap which had been separated from the chest was extremely thick and heavy. When an attempt was made to move the fingers it appeared as though there was a large amount of scar tissue holding the tendons at about the level of the annular ligament.

On December 12 at New Asbury Hospital, the pedicle flap was loosened and a large amount of fat, with some skin, was removed. At that time the area which had practically nothing but scar tissue between the muscles and tendons, had a group of tendons completely down through the fatty tissues. The fat tissue posterior to the scar tissue and tendons was well preserved. There was a mass of scar tissue at the lower end of the pedicle flap. Adhesions were freed and a closure of the wound was performed. Incision was made laterally to the ulna and the distal end of the ulna resected. Since this time she has been making very nice improvement again. There was impairment of function for a few weeks after the last operation. Pronation and supination has increased since December 12. She can now flex the fingers so that the fingers almost touch the palm of the hand. Abduction and adduction of the fingers is not quite as good as previous to the last operation, but is improving constantly from week to week, so that ultimately it will probably be very nearly normal. On account of the contraction of the flexor tendons the fingers can be completely extended only when the hand is flexed. It is also noted that the hand is very much smaller than the normal hand.

The striking feature about this case was the fact that nerve suture was performed one year and eight months after the original injury. The opinion prevails that nerve suture after eighteen months gives practically no results. However, here is a case which shows practically complete restoration of function, with suture being performed one year and eight months after the original injury or severance. Whether the destroyed epiphysis of the radius in this case was caused by infection or the injury, is difficult to say. However, it impaired the growth of the bone in the radius. The other striking feature is the fact that tendons which were not present at the time of the first operation in August, 1926, have grown or regenerated down through the fat so that there was a mass of tendons extending down through the fatty tissues.

This girl is normally a right handed individual. Since her injury she has educated her left hand so that now she is practically a left handed individual.

Discussion

Dr. Kenneth Bulkley: It was with considerable pleasure that I had the opportunity of seeing this patient in consultation with Dr. Bratrud a short time before he operated upon her for the second time, and also to have again had the opportunity of examining her a few days ago. Dr. Bratrud is to be congratulated on obtaining so useful a hand for a patient who originally seemed to have a hand hopelessly crippled as far as any real use of it was concerned. This case should not only serve as a lesson in optimism to us, but can also be used as a text for a few remarks on four different problems which it illustrates.

The first relates to the viability of transplanted fat. There has long been a controversy, more or less, as to whether transplanted fat remains as such or gradually undergoes fibrosis. I believe this case illustrates the fact that it does maintain its identity and viability. The

first full thickness transplant which Dr. Bratrud made and the remains of which you now see was infinitely thicker than it now is, since Dr. Bratrud at the second sitting dressed it down. The pad was characteristic, soft and pliable, and Dr. Bratrud informs me that at operation there was very little, if any, signs of fibrosis in it.

The second problem relates to tendon regrowth or which might possibly better be termed tendon refunction. Dr. Bratrud informs me that when he first operated upon this girl some 11 years ago at the point where the tendons emerged from the fleshy bellies of the flexor muscles they disappeared into a mass of what appeared to be fibrous scar tissue, and you will remember that he made no attempt to separate these, if they existed, one from the other, but simply undermined this mass of scar tissue, interposing fat beneath it and also superficial to it beneath his skin flap; and yet you have seen demonstrated tonight how a hand, practically useless in the form of a "claw," has re-educated or re-differentiated or possibly, to a certain extent, regrown its tendons so that at least to a very serviceable extent they now function.

The third point of interest in this case to me seems to be the lack of growth of the radial epiphysis, which is probably more common in fractures of the ends of the long bones in children than is generally recognized. Compere,* in a recent report from Chicago, has investigated the growth arrest in long bones after fractures including the epiphysis. About thirty-five per cent of all fractures that had been treated in his Clinic occurred in children fourteen years or younger and fourteen per cent of these fractures in children involved the growth epiphysis; and of these involved cases that were cared for and followed over a period of six months with x-rays, ninety-five per cent of them showed growth disturbances. The method used by Dr. Bratrud in each operative sitting for the correction of this radial deviation by resection of a portion of the ulna is the classical procedure commonly used.

To me the most astounding result obtained in this case was the regeneration of both the median and ulna nerves. You will remember that this girl suffered her primary injury south of the southernmost tip of Africa and was not operated upon here in Minneapolis by Dr. Bratrud until approximately twenty months later. If I understand the situation correctly the median nerve was found completely divided and an end-to-end anastomosis was necessary, with marked flexion of the wrist thereafter in order to bridge the defect which so commonly occurs in these nerve divisions; and yet nine months later this girl was already beginning to show signs of regeneration and today she has complete regeneration of her median nerve. This is an almost unheard of result as far as I know for nerve regeneration where the repair has been made later than the sixth or at most the ninth month following severance. The regeneration of the ulna nerve is possibly easier to understand inasmuch as I believe it was not completely severed but merely thoroughly embedded in scar tissue, requiring only a neurolysis.

In view of the fact that no one of us as individuals see any large number of nerve trunk injuries, possibly it would be of value to refresh our memories as to what goes on in the regeneration of a nerve trunk, and for that purpose I am going to close my discussion by quoting Campbell† on the subject:

"After complete or partial severance the ruptured nerve fibres separate; the distal segment loses its function and undergoes degeneration. The injury produces an effusion of blood, and migration of leukocytes takes place into and about the end of the proximal segment and throughout the entire distal segment. The axis-cylinders perish, the myelin sheath is absorbed and the cells along the inner surface of the neurilemma cease to proliferate. The sheath shrinks and becomes empty except for scattered masses of nuclei and protoplasm. The degeneration occurs rapidly, beginning within twenty-four hours after the injury, and is complete in a few days. The leukocytes are replaced by connective tissue cells which absorb the fatty myelin and the axis-cylinders, and the degenerated nerve trunk becomes hard, fibrous and cirrhosed. In the proximal end of the divided nerve, an end-bulb is formed by curling up of the prolonged nerve fibres and fibrous tissue. While degeneration occurs in a few days, regeneration requires months. The exact method of regeneration is uncertain. Partial regeneration undoubtedly occurs in the distal segment, independently of the proximal, although complete regeneration is not possible unless the two segments are in apposition. The generally accepted theory is that the nerve is regenerated by the prolongation of the existing nerve fibrils in the proximal segment. The fiber, which is at first composed of myelin, pierces the granulation tissue between the nerve ends and enters into the empty sheath of the distal segment. It grows slowly along the scaffold of the degenerated trunk and function is re-established only when the new axis-cylinders have permeated the nerve."

Dr. S. T. Maxeiner: I realize that most reports of late nerve suture are not encouraging and nerve suture of long standing is often condemned. However, I would call your attention to the Clinic given by Dr. Kanavel before the American College of Surgeons in Chicago, at which time he reported a nerve suture in the case of a Seattle surgeon five years after the original injury. Regeneration was extremely slow but was progressive over the next five-year period and became so complete that the doctor is able to do his own surgery. This would suggest that nerve suture performed after the lapse of five years is not entirely hopeless.

Dr. G. R. Dunn: I certainly think that Dr. Bratrud is to be congratulated on this case. This case presented most unusual difficulties, the establishing of full thickness skin graft, freeing of the tendons, suturing of the nerves and correcting the growth disturbance. Each and every one of these procedures is difficult and that the four procedures should have given such an excellent functional result is quite remarkable. I think it is one of the best cases of this sort I have had the pleasure of seeing.

PRESENTATION OF A CASE WITH A LARGE CAVITY IN A POSTOPERATIVE LUNG ABSCESS WITH MULTIPLE LARGE BRONCHIAL FISTULÆ

W. A. Hanson, M.D.

Mr. E. N., thirty-seven years of age, married, was seen by us in February, 1934, with the following history. His past history and illnesses were irrelevant. He stated that while in the Orient at Java, on October 7, 1929, he was acutely ill and was operated upon for acute appendicitis. He was discharged from the hospital at the end of ten days feeling well. Four or five days later he began to have pains in the right chest followed by a persistent unproductive cough. The symptoms persisted more or less until January, 1930, when his cough became productive with a large amount of sputum, and "probably associated with a fever." At this time he was informed that he had "pleurisy." His weight had decreased from 145 to 115 pounds. During his travels from Hongkong, Shanghai, and Japan his cough became more persistent and at this time he raised considerable sputum

*J.A.M.A., 105:2140-2146, Dec. 28, 1935.

†Campbell: A Textbook of Orthopedic Surgery, 1930.

and "decayed lung tissue." His condition was diagnosed as tuberculosis. Radiographs of his chest were interpreted as bronchiectasis. Following this he began to raise blood and pus in his sputum. At Manila his right chest was aspirated, obtaining "pus and water," and he was informed that he had a lung abscess.

Fig. 1.

He returned to the United States in August, 1930. He raised a pint of sputum in each twenty-four hours, consisting of blood, pus, and mucus, which had a foul odor. Following bronchoscopy a diagnosis of bronchiectasis was made. He had a continuation of his symptoms until December, 1930, when he had a rather profuse hemorrhage from the lung. Following this he had aspirations of the chest and a series of posterior rib resections with beneficial results. Subsequently he developed a large cavity with bronchial fistulæ, which we wish to demonstrate this evening.

At this present time, his physical examination shows a well developed male who weighs 142 pounds and is 5 feet 6 inches tall. His blood pressure registers 110 systolic and 70 diastolic in mm. of mercury. His pulse is 72 beats per minute and his temperature is 98.6°. The examination of the head, eyes, ears, nose and throat reveals no abnormalities. The fingers reveal a moderate clubbing, characteristic of chronic lung disease. The right chest in the subscapular area shows a large cavity about the size of two navel oranges with many fibrous strands and bronchial fistulæ. One fistula communicates with the main hilus bronchus. The wound shows no evidence of infection. This is packed daily. On removal of the packing he is very dyspneic and is unable to talk above a whisper. The left chest is free from abnormalities. Examination of the urine is negative. His blood shows a hemoglobin of 78 per cent (Dare) and 4,100,000 red blood cells per cubic millimeter of blood.

Radiographs taken of the chest show no abnormality in the left lung field. The right chest shows resections with partial regeneration of the fifth, sixth, seventh, eighth and ninth ribs. There is a partial collapse of the lower lobes and thickened basal pleura.

Comment.—This case is of interest first because of the past and present disease and second from the standpoint of what method would be most efficacious in closing the large cavity and large fistulæ.

According to Dr. Carl Hedblom's collected series of 686 cases of lung abscess, 71 per cent occur in males and 29 per cent in females, except in those occurring after tonsillectomy, where the incidence was 43.9 per cent in males and 56.1 per cent in females.

The recognized causes of lung abscess are:

1. Aspiration through the bronchial tree.
2. Pneumonia.
3. Embolism.
4. Extension from other foci such as subphrenic, liver, perirenal, etc.
5. Trauma as by a blunt blow on the chest wall, with the onset of the disease varying from one to five weeks. Stab wounds and penetrating injuries may manifest such complications months or years after the original injury.
6. Specific infections such as actinomycosis ameba histolytic, etc. Tuberculosis cavities are not included.

A further consideration of the symptoms, pathology and findings will not be reviewed, as they are ably discussed in the textbooks, other than to state that this patient probably developed his complication from an embolism, although ascending infection cannot be disregarded.

Regarding the treatment of lung abscess, several procedures are available. An ingenious, rather simple method has been devised by Dr. O. H. Wangensteen and reported in the *Journal of Thoracic Surgery* for December, 1937. Dr. Wangensteen employs needling, graduated trocars, coagulation and drainage. Dr. E. A. Graham's method with a cautery is recommended in certain cases with good results. These depend on fibrosis of the visceral and parietal pleura with drainage.

The method to accomplish the closure of the large cavity and multiple fistulæ under consideration in this case may be: (1) obliteration of the strands of adhesions with cautery and conversion of the cavities into one pocket; or (2) further thoracoplasty for obliteration of the cavity employing muscle implants to close the fistulæ.

Discussion

Dr. T. J. Kinsella: I was very interested in seeing this patient of Dr. Hanson's. He certainly presents a condition which we do not see frequently. He now has multiple bronchial fistulæ which are, in reality, the residue of bronchiectatic abscesses with their bronchial openings. This lower lobe is nothing more or less than a honeycomb and this type of condition, once it occurs, is permanent. It will not clear by itself and it will not clear with bronchoscopic drainage. A single drainage tube inserted into a lung of this sort does not drain the abscesses because they are multilocular and not one single pocket. The only way you can handle this sort of condition is either to resect the lobe involved or to do a Graham cautery for external drainage, creating multiple bronchial openings to drain the pus externally rather than to let the patient cough it up. In the presence of an empyema, primary resection of the lower lobe containing the bronchiectatic abscesses would be inadvisable because it would undoubtedly result in contamination of the mediastinum and probable loss of the patient.

Drainage of these abscesses is necessary and the Graham cautery in the presence of an infected pleural cavity or an empyema offers one method of obtaining drainage and relieving the patient of his symptoms without the risk of dissemination of the infection. It does leave a rather nasty condition in the chest, in that you now have multiple pockets, communicating with your operative wound, and all of the pus which originally drained up through the bronchus now comes out or through the wound. After a period of time, however, the infection subsides, but the pockets still remain. The secretion diminishes, leaving an epithelialized tract or series of pockets which produce very little discharge. If you now surgically close up this wound, while there are still abscess cavities present, even though they contain no pus, you will probably induce a recurrence of the trouble. This man now has multiple pockets which are relatively clean and show little or no pus ordinarily, but if they were closed up by an external plastic collapse procedure he would undoubtedly develop cough and expectoration and have further difficulty.

This man, as he walks around, is not short of breath and can work, if he carries a tight pack in his wound. If he does not have a tight pack in his wound he can scarcely speak above a whisper for most of his air comes out through the external openings. He then loses his wind and is not able to work. From a surgical standpoint, there are two or three things which might be attempted. One is to convert all of these abscesses into one single pocket and then do an external collapse procedure to bring the walls into contact to allow healing. A muscle transplant might be turned into the pocket to attempt to close the bronchial fistulæ, but this is rather a difficult thing to do in this instance. Much of the muscle on the back of his chest has been destroyed in the previous surgical procedures, leaving very little for a transplant into the fistulæ. Smaller fistulæ may be closed by cauterization with silver nitrate, leaving a clean wound which will close by external plastic procedure. If the fistulæ cannot be closed, and many of the large ones do not close readily, then you are confronted by a very complicated proposition which may demand all your ingenuity and maybe more than that to get rid of it. In some instances it may prove wiser to let well enough alone and let the patient continue to work with his chest wall defect.

Dr. Owen Wangensteen: There are two matters of great interest in the case presented by Dr. Hanson: one is the question of the etiology of the suppurative process in the lung which eventuated in the condition which Dr. Hanson has shown us; the other revolves about the more important consideration of treatment.

Both Drs. Hanson and Kinsella indicated that they believed the process to have had its origin through an embolic source—a thesis for which a plausible defense may be prepared. Yet, I am inclined to believe that this was an *ascending* rather than a *descending* infection. The patient, as Dr. Hanson stated, had an appendectomy for suppurative appendicitis: he left the hospital ten days later while he was still ill; he continued ill and lost weight from 145 to 115 pounds. My reaction would be that a subdiaphragmatic abscess developed, which subsequently penetrated the diaphragm and lay outside the lung for a long time as an occult empyema. Only after a lapse of about fifteen months did the abscess rupture into the lung, signalled by the spitting up of large quantities of sputum. Subsequently, the pulmonary abscess ruptured into the pleural cavity at a site where there was a free pleural space, for, as Dr. Hanson said, the patient became suddenly much worse and when the pleural cavity was aspirated, considerable exudate was obtained. There having been no evidence of pulmonary suppuration earlier in life we can disregard primary bronchiectasis as a consideration—other than as an occurrence secondary to long continued pulmonary suppuration.

This interpretation of the story which Dr. Hanson related may appear a bit unusual. At this remote date, one can only speculate as to the probable sequence of events. But mindful of the long period of time intervening between the initial suppurative process in the appendix and the first suggestion of pulmonary suppuration, I do believe the facts as stated lend considerable weight to the ascending view which I have taken of the matter.

At the present moment, I have at the University Hospital a young woman who was operated upon for suppurative appendicitis three years ago. A subdiaphragmatic abscess developed and was drained. In the intervening years, she had continued to complain of pain near the spine at the level of the tenth to twelfth dorsal segments. A sinus has opened intermittently; it has been enlarged and explored but nothing has been found. On opening the tract widely, recently, I uncovered an occult empyema beneath the tenth and eleventh ribs. It had not yet ruptured through the lung to establish communication with a bronchus. More commonly, of course, the development of a pulmonary abscess follows closely upon the formation of the subdiaphragmatic abscess. Most of you, I am certain, are familiar, however, with the occurrence which I have described.

Drs. Hanson and Kinsella have considered the therapeutic agencies which one might invoke to close the bronchial fistulæ which the patient now has. In the light of the satisfactory condition of the patient and his relative freedom from discharge from the fistulæ, I would agree that an attempt should be made to close them. As Dr. Kinsella has pointed out there has been already considerable loss of available muscle tissue immediately adjacent to the fistulous openings. Whereas, implantation of a pedicled slip of muscle into a bronchial fistula or suturing a flap of muscle over the stomata is a very useful procedure and one to which I am quite partial (Journal of Thoracic Surgery, 1935:5: 27), I am inclined to believe that it would be difficult to make such a plan work here. Even though a suitable pedicled muscle flap might be mobilized to fill in the defect, it would be even more difficult to cover the defect and transplant muscle with skin satisfactorily—a very important consideration in the closure of these numerous and large bronchial stomata. The best plan of procedure, I believe, is the procedure of Lebsche (Deutsch Ztschr. f. Chir. 189, 279, 1925).

While Professor Sauerbruch was still at Munich, his assistant, Lebsche, described a very useful technic for dealing with numerous bronchial stomata, which condition he described as "Gitterlunge" or gridiron lung. The margins of the exposed lung are mobilized by freeing it from the adjacent skin and other structures. The margins of the mobilized lung are then sutured together, burying the stomata. It is wise, I believe, to insert a temporary drain (*Surgery*, 2:859, (Dec.) 1937, footnote) led off through sufficient thickness of the chest wall, such that a persistent fistula is not likely to form. The skin is then closed securely over the trough of inverted lung tissue.

In order to secure adequate relaxation of the structures of the chest wall to permit satisfactory skin closure over the plastic on the lung, it would be well, I believe, to perform here a preliminary resection of the third, fourth and fifth ribs anteriorly two or three weeks before. It is my impression that the Lebsche procedure for "Gitterlunge" would offer the most satisfactory solution in closing this unusual defect.

INTERNAL FIXATION IN INTRACAPSULAR FRACTURES OF THE NECK OF THE FEMUR

Willard D. White, M.D.

Summary

The general problem of treatment of intracapsular fractures of the neck of the femur was discussed. Statistics were given on the mortality, which probably averaged about twenty per cent in patients over fifty years of age who were treated by the old Whitman method or other non-operative means. The mortality increased in direct proportion to the age. As to percentage of unions in the so-called conservative or non-operative treatment represented by the Whitman or Maxwell-Ruth methods, this was not over fifty per cent. In many series the percentage was less.

There have now been enough cases operated upon by internal fixation to give some idea of its success. The method is still comparatively new and it is difficult to establish accurate statistics but there is no question about the fact that the mortality has been decreased and the percentage of unions very markedly increased. There are further advantages in the economic saving and the increased comfort to the patient.

Lantern slides were shown to illustrate pre-operative and post-operative results and patients were presented, all of whom had been operated upon at least a year ago or more. It was demonstrated how these patients could walk, move their joints, et cetera. Some of the hazards or risks were discussed.

Twenty-four cases in which the author performed an operation were discussed. In the first eleven a reduction was accomplished, position checked with antero-posterior and lateral films, a Kirschner wire was inserted and a canulated short flange nail was inserted over the wire and driven into place. In one of these cases the wire bent, in another the wire broke and was driven in through the acetabulum into the pelvis and had to be removed from within the pelvis. Following this, twelve patients were operated upon and the joint opened, the fracture reduced under direct vision and the nail also driven in under direct vision. In the last case the nail was driven in directly through a lateral incision over the trochanter without the preliminary introduction of a wire. The position of the nail was perfect.

Many of the cases are too recent to warrant a report on final results but it was felt that the operative treatment of intracapsular fractures of the neck of the femur with internal fixation offered by far the best means we have to treat this lesion. In the main, a short flange nail of the Smith-Peterson type was used. It is admitted that other types of internal fixation would probably accomplish the same results. In two cases Austin Moore pins were used and were very satisfactory.

Discussion

Dr. E. A. Regnier: Dr. White has covered the field of internal fixation of fractures of the neck of the femur most thoroughly and I assure you he is not the only one who has made a mistake of judgment and of technic. One must appreciate that internal fixation does not assure a union but rather it insures union. Obviously, there are many methods by which this may be done. I believe, in the light of my short experience, that even though the end-results by internal fixation were no better than those from previous methods, I should still choose the former method because of the absolute relief from pain and the financial saving it affords the patient. When one recalls that these patients were formerly hospitalized twelve to sixteen weeks and in the best hands only 50 per cent of those who survived treatment had satisfactory results, an improved method of treatment is most welcome.

Dr. White mentioned the various methods that he had used in treating these fractures. I believe that the choice of method is optional. It has been my practice to do a closed reduction and subsequently to make a short incision laterally below the trochanter so as to drive the nail over the previously inserted Kirschner wire. I have always attempted to place the nail in a valgus position because this permits less strain on the line of fracture. I believe that the Austin Moore pins, flanged screws and Morrison pin will all maintain fixation but I do not believe that they are compatible with any degree of early unprotected walking. At the General Hospital our patients could not afford walking calipers, therefore we permitted them to walk with crutches two weeks after inserting Smith-Peterson nails. These people were permitted to go home any time after the third week and we soon learned that many of them discarded their crutches soon after leaving the hospital and walked on the nailed hip long before union could take place. I recently had an opportunity of seeing a follow-up x-ray of a man whose hip I nailed one year ago and who has been walking without protection ever since. I will show his film and I think you will agree that he has a perfect union in excellent position. I also had the privilege of nailing the hip in an eighty-six-year-old woman and she was permitted to walk without protection the week following her operation. She has now walked for seven months without any mishaps and is perfectly comfortable. However, I do not advocate unprotected walking short of four to six months. I believe it is perfectly safe to put a properly fitted walking caliper on these people as soon as their wounds are healed. I have done this on over thirty cases and have had no occasion to regret it. The youngest patient that I treated was thirty-eight years of age and the oldest eighty-six. There has been no mortality and up to date only one case has proven a failure. In this individual the head of the femur partly atrophied and rotated off the end of the nail, necessitating a reconstruction operation.

Internal fixation should maintain accurate anatomical reduction and relieve all pain. The relief of pain has been so immediate and so gratifying that it has been my practice to treat these immediately, as soon as the immediate shock of fracture has been relieved, usually a matter of twelve to twenty-four hours. Nothing can be gained by postponing operation. Many old people

fail rapidly when confined to bed with Buck's extension and morphine to control their pain while awaiting operation. I believe that the small risk and minimal trauma from the operation more than offset the risk of postponement. They are less apt to develop pneumonia and have much more freedom and comfort after operation than before. I believe that this procedure will soon be recognized as a routine and practically an emergency operation. In other words, unless a patient is moribund or has some complicating disease such as severe diabetes, I can see no reason for postponing the insertion of a nail in a recent fracture. (Films were shown.)

Dr. V. Hart: There are a number of remarks I would like to make but the hour is late so I will just close by telling Dr. White that I have appreciated his instructive paper and that I heartily support his thesis.

Dr. E. T. Evans: I won't say anything about the methods of treatment, et cetera, because I think that internal fixation of the neck of the femur is here to stay. I think, however, that we have much to learn in cases such as this. In spite of the fact that Dr. White said he hesitated to give a report at such an early date this is probably worth much more than a series of cases with beautiful results, for it is by our mistakes that we are to learn. Dr. Cole and I have now done something over forty hip operations in the last year by the open method, not Watson Jones approach but Kocher's anterior fascial splitting approach, and with the exception of two or three cases we feel we have learned something on every hip we have done. We are becoming more and more convinced that in our open reductions we are obviating some of the difficulties we have seen tonight and that is said with the experience of two or three years of closed reductions in back of us. It doesn't mean that we won't switch back to the closed reduction because we are open to conviction that with some improvements in technic the closed reduction may offer the same results.

Harvey Nelson, *Secretary.*

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

BOOKS RECEIVED FOR REVIEW

Workbook In Elementary Diagnosis for Teaching Clinical History Recording and Physical Diagnosis. Logan Clendening, Professor of Clinical Medicine, University of Kansas. 167 pages. Illus. Price, cloth, $1.50. St. Louis: C. V. Mosby Co., 1938.

Men Past Forty. A. F. Niemoeller, A.B., M.A., B.S. Author of American Encyclopedia of Sex, etc. Foreword by Winfield Scott Pugh, B.S., M.D. 154 pages. Price, cloth, $2.00. New York: Harvest House, 1938.

Management of the Sick Infant and Child. Fifth Edition. Langley Porter, B.S., M.D., M.R.C.S. (Eng.), L.R.C.P. (Lond.), Dean, University of California Medical School and Professor of Medicine, etc., and William E. Carter, M.D., Director University of California Hospital Out-Patient Department, etc. 875 pages. Illus. Price, cloth, $10.00. St. Louis: C. V. Mosby Co., 1938.

A Biological Approach to the Problem of Abnormal Behavior. Milton Harrington, M.D., Psychiatrist, Institution for Male Defective Delinquents, Napanoch, N. Y. Formerly Consultant in Mental Hygiene, Dartmouth College. 459 pages. Cloth. Lancaster, Pa.: Science Press Printing Co., 1938.

Pneumonia and Serum Therapy. Revised Edition. Frederick T. Lord, M.D., Clinical Professor of Medicine, Emeritus, Harvard Medical School; Member Board of Consultants Massachusetts General Hospital, etc., and Roderick Heffron, M.D., Field Director Pneumonia Study and Service, Massachusetts Department of Health. 148 pages. Price, cloth, $1.00. New York: The Commonwealth Fund, 1938.

THE 1937 YEARBOOK OF GENERAL MEDICINE. Chicago: Yearbook Publishers, 1937. $3.00.

The 1937 volume of the Yearbook of General Medicine is, as usual, an excellent piece of work. Most of the important developments in the field of internal medicine that have been brought forward in the past year have been reviewed. Of special interest to our own readers is the fact that among those authors mentioned we find the names of Drs. Lufkin, Mariette, Myers, Shapiro, Wangensteen, Cecil Watson and Ziskin.

The volume can, indeed, be recommended to all those interested in a general review of the important work of the past year.

PREVENTION OF SPONTANEOUS AND INDUCED ABORTION*

FRED J. TAUSSIG, M.D.
Saint Louis, Missouri

NOWADAYS we hear much talk about the conservation of our natural resources, reforestation, soil-preservation, and the control of damage by flood and famine. Not so much thought is given, however, to the even more important problem of conservation of our human resources. It is up to us as physicians to take the leadership in that direction. I know no more glaring example of the failure to practice conservation than in the wastage of human life associated with spontaneous and induced abortion. The avoidance of a pregnancy through contraception may limit production but it does no physical harm. Childbirth involves certain unavoidable risks to both mother and child, but there is the compensation of a new life added to our human resources. Abortion, on the other hand, has all these risks multiplied seven-fold without any of the compensations. With the exception of a small number of therapeutic abortions, it has nothing but liabilities as its sequel: the mother incapacitated, her health undermined at times, with death not an infrequent termination. The prevention of abortion therefore demands our most serious consideration.

Approximately six to seven hundred thousand abortions occur annually in the United States, and probably eight to ten thousand women lose their lives annually as a result of this condition. These estimates give one a conception of the magnitude of the problem. About one-third of these abortions are spontaneous and two-thirds are induced. Elsewhere[20] will be found the data, still rather meagre, upon which these figures are based. I shall confine my remarks solely to the matter of causes and prevention.

Spontaneous Abortion

The more grateful portion of this study, because holding better promise for its relief, is that of spontaneous abortion. Here we have the eager coöperation of the patient and the measures employed are strictly medical, involving tests, examinations and procedures which are entirely within our own scope as physicians, as distinguished from the problem of induced abortion, in which the legislator, the economist and the social worker have an almost equal share of responsibility in preventive measures.

Since 1909 when I first ventured to write a brief monograph[21] on the "Prevention and Treatment of Abortion," there has been a definite advance in our knowledge of the causes and prevention of spontaneous abortion. At that time almost all abortions were attributed to some physical accident or trauma, and rest in bed together with the hypodermic administration of opiates were the only remedies used to combat the premature interruption of pregnancy. Habitual abortion was attributed to syphilis and patients were routinely placed on anti-luetic treatment. In the past three decades our increasing knowledge of the endocrine secretions and their modification during pregnancy has opened up a whole new field in the study of sterility and early abortion. Although we are far from having solved this problem, certain experimental data and clinical results point to the fact that we are at least on the right track and that the next decade should bring about a considerable reduction

*Read, by invitation, before the Hennepin County Medical Society, Minneapolis, January 3, 1938.

in the number of spontaneous abortions in those patients who can and will coöperate in carrying out the rather tedious and expensive method of treatment at present available.

Certain fundamental facts regarding the predisposing factors in spontaneous abortion have always been recognized. The general physical condition of the mother, more especially the condition of the uterus, in which the impregnated ovum was implanted, should be as near to normal as possible. Not infrequently pregnancy continues in spite of marked pelvic disease, but certainly the incidence of abortion in these cases is far in excess of the average. It has therefore been our aim to put the uterus in as normal a condition as possible.

Physical factors predisposing to abortion are: (1) retroversion; (2) fibroid tumors; (3) septate or infantile development; (4) deep lacerations of the cervix; (5) endometrial hyperplasia.

Since these causes have in the past been fully discussed, they will be considered only briefly in this paper. A considerable majority of retroverted uteri will rise out of the pelvis as pregnancy advances without complication. Nevertheless, gentle methods of bringing the uterus forward and holding it there with a pessary decrease uterine irritability and the chance of abortion. Gentleness is essential, however, since brusque manipulations predispose to interruption of the pregnancy. In the presence of fibroid tumors a decision will often be difficult, since pregnancy is ordinarily not interrupted. Where abortion has occurred without other apparent reason, it will usually be wise to do a myomectomy before allowing another pregnancy to take place. Septate and infantile uteri present physical conditions limiting the proper stretching of the uterine cavity. In the former, surgical excision of the septum is advisable. The infantile uterus may require no further treatment, since the pregnancy, even though terminating in abortion, has usually so dilated the cavity that a subsequent gestation is readily carried to term. Deep lacerations of the cervix may tend to abortion by predisposing to dislodgment of the lower pole of the ovisac, to decidual hemorrhage and decidual infection. They should in certain cases be repaired preceding a further conception. Endometrial hyperplasia, often a sequel of postabortive endometritis, may lead to renewed abortion if not corrected by a curettement. It can result in faulty implantation of the ovum and so to fetal death.

Turning now from pelvic disorders to systemic infections as factors in abortion, two deserve special attention: (1) focal infections; (2) syphilis.

Curtis,[8] Reith[17] and others have demonstrated the occurrence of abortion in women who have a focus of infection, especially about the teeth or tonsils. Certain strains of streptococci, both in animals and humans, apparently predispose to decidual infection and abortion. Elimination of points of infection before the occurrence of the next pregnancy is therefore advisable. It would also be logical to give sulphanilamide in such cases, though I know of no reports in which this has been tried.

Syphilis is relatively simple of recognition and control, even though it is generally recognized that in the white race it rarely produces fetal death and interruption of pregnancy previous to the fifth month. In every case of abortion, however, it is wise to do a Wassermann test on husband and wife, and, if positive, institute specific treatment. McCord[9, 10] has shown that in the negro the virulence of syphilis may cause fetal death and abortion even in the first half of pregnancy.

It has been customary in the past to distinguish between maternal and ovular causes of abortion. In my recent book I still clung to this classification. The more we appreciate the close relationship between the endocrine secretions on the one hand, and the development of the ovum, its impregnation and implantation, and the associated irritability of the pregnant uterus on the other hand, the less does such a separation seem logical. The careful study of abortion ova, begun forty years ago by Mall[11] at the Carnegie Institute of Embryology at Baltimore and since then carried out in many other places, has brought convincing evidence of the importance of arrested development in the production of abortion. In fact I do not believe it an exaggeration to say that in two-thirds of spontaneous abortions such an abnormality of the hormonal secretions is the fundamental contributing cause. We have for a long time been skeptical about the stories of falls, strains, blows and other forms of trauma to which abortion has been attributed, since these injuries are relatively frequent during pregnancy and only in certain individuals seem to be

attended by an expulsion of the ovisac. Sexual intercourse in the first trimester of pregnancy seems more definitely a contributing factor in abortion, but here it is plausible to assume that the physical contact may be less important than the associated stimulation of hormonal activities.

I shall consider the subject of endocrine pathology under three heads:

1. Preconceptional conditions influencing the development of the sex cells (ovum and sperm).
2. Developmental factors influencing the implantation and the nutrition of the ovum in the first trimester of pregnancy.
3. Hyperirritability of the uterine muscle, due directly or indirectly to an improper balance of endocrine secretions.

Preconceptional conditions.—It has long been noted by veterinarians and those engaged in animal experimentation that low fertility is usually attended by a high abortion rate. The bull with abnormal spermatozoa will produce a high percentage of abortions in his herd. The ovum is also frequently at fault, so that, if impregnated, its development will not progress beyond the stage of a primitive egg-mass. There is good reason to believe that many such abortions in women are not recognized but pass as an abnormal menstruation, since they do not materially disturb her physical condition. The more carefully we examine every extruded ovum in spontaneous abortions, the more we are impressed with the frequency of these so-called "blank cartridges," an unruptured amniotic sac in which no trace of embryo is longer visible. Occasionally a little nubbin of tissue will show a degenerated embryonal cell-mass. Such primarily blighted ova are frequently associated with relative sterility of the couple. Kane[6] found that of thirty-six children born to forty mothers who had previously habitually aborted, three showed malformations, and concludes: "It may be that preventing the expulsion of abnormal fetuses in the early months of pregnancy is combating nature's provision for the elimination of the unfit."

Unfortunately our knowledge of endocrine diagnosis and treatment is still in its infancy. We must grasp at straws in our preventive measures. The quantitative tests for estrogenic substance are not suitable for routine laboratory work. The basal metabolism test is our mainstay in this work. If such a test indicates a hypothyroid condition in either husband or wife, it has been found that thyroid extract in moderate doses contributes both to increased fertility and to a more healthy ovum and sperm, so that the resulting impregnation is less apt to be followed by an abortion. Even with a relatively normal basal rate, it would seem that the pre-conceptional ingestion of small amounts of thyroid does no harm and may be of benefit.

Occasionally there have been observed mismated couples, who are sterile or have repeated abortions. In subsequent marriages both husband and wife may have healthy offspring. Tranquilli-Leali[22] has ascribed such a condition to incompatible blood groups. In thirty-eight of forty-one cases of habitual abortion he found husband and wife belonging to different blood groups. Further observations are required before we can definitely accept this hypothesis as true.

A routine careful examination of the spermatic fluid constitutes the most important point in preconceptional diagnosis and treatment. If this shows faulty morphology and motility, all possibly contributing causes, such as prostatic infection or endocrine disorders, should be corrected before allowing conception again to take place.

Developmental factors influencing the implantation and nutrition of the ovum, center largely around the proper functioning of the corpus luteum of pregnancy. Removal or destruction of this portion of the ovary shortly after conception invariably results in abortion, as proven by animal experimentation. Unfortunately we have as yet no quantitative physiologic test for the hormone produced by the corpus luteum, hence both our diagnosis and treatment must be largely empiric. We know that the corpus luteum has a sedative effect on the uterine muscle just as anterior pituitary and estrogenic extracts have a stimulating effect. Consequently in cases of abortion not explainable on any other basis we assume a deficiency of corpus luteum or excess of estrogenic or anterior pituitary hormone. It seems fairly certain in any event both by animal experimentation and clinical experience that the injection of large amounts of progesterone (luteinizing hormone) in the early months of pregnancy does no harm and in a surprisingly

large percentage definitely inhibits the tendency to abortion. Novak[13] rightly calls attention to the cases in which sedatives and rest without further medication prevent abortion, but in the forty-one cases of habitual abortion treated by Falls, Lachner and Krohn[5] the patients were up and around and received only progesterone with successful continuation of pregnancy to term in thirty-four cases. In Kane's series of forty cases of habitual abortion thirty-six were carried to term by the use of progesterone, but in this series thyroid extract was also given.

Whether this favorable effect of progesterone is primarily due to the prevention of an insufficient decidual reaction predisposing to faulty implantation or whether it is the countervalent in women who produce an excess of estrogenic or pituitary hormones remains at present unsolved.

In similar fashion we have abundant clinical evidence of the favorable effect of thyroid extract in preventing abortion, but we do not know in what way it acts. Many of these patients have a low basal metabolic rate. Werbatus,[25] treating twenty-four cases of habitual abortion with thyroid extract alone, reports only one failure. Aza[1] also speaks of good results with this treatment, and Litzenberg[8] stresses the value of thyroid extract in the treatment of sterility and abortion.

The interdependence of metabolic processes and the internal secretions is at no time more evident than during pregnancy and plays an important part in the etiology of abortion. E. C. P. Williams[26] has called attention to the frequency of low sugar tolerance in women who habitually aborted and found that by proper dietary control with or without insulin the incidence of abortion could be reduced. Vogt-Möller[23] and more recently Shute[19] have stressed the importance of a diet rich in Vitamin E. Vogt-Möller found a very low cholesterinemia present in habitual abortion and found that the administration of Vitamin E, in the form of wheat germ oil, corrected this condition and resulted in fifty-seven out of seventy-four cases being carried to term. Shute found that in many cases of spontaneous abortion the blood serum was resistant to tryptic proteolysis. This condition of the blood serum could be produced in rats by putting them on a diet devoid of Vitamin E. Hence he gives this vitamin in large amounts to patient having repeated abortions and found that the proteolytic reaction of the blood became normal and the pregnancy was carried to term. Shute believes that Vitamin E is one of the factors in the body that holds estrogenic substance in equilibrium during normal pregnancy.

The ingestion of large amounts of Vitamin C in the form of cantan has been advised by W. Schmidt,[18] since it has been claimed that this vitamin improves the function of the corpus luteum. He believes that in this way the tendency to abortion is reduced. Some writers stress the significance of calcium deficiency as a factor in abortion.

Hyperirritability of the uterine muscle, due directly or indirectly to improper balance of the endocrine secretions, has already been touched upon in the preceding paragraphs. Whether in these cases we are dealing with an excessive amount of estrogenic or pituitary hormones or an insufficient quantity of corpus luteum hormone it is difficult to say. In all events the hyperirritable uterine muscle under these circumstances, if subjected to any form of physical or psychic excitation, begins to undergo rythmic contractions that loosen and finally detach the placenta from its point of implantation, thus leading to an abortion. This cycle may occur at any time in the first two trimesters of pregnancy but is more apt to occur at the time of the expected menstrual period. At approximately four weeks intervals following the last menstruation there still persists a menstrual-like wave, at which time the uterus is more irritable and abortion more apt to occur. Exciting factors leading to abortion in such a hyperirritable uterus may be some physical strain or trauma, sexual intercourse, nervous exhaustion or mental shock. In some cases the period of greatest danger from abortion for some reason may be as late as the fourth or fifth month of gestation, hence it is advisable to continue the hormonal administration up to the period of viability of the child.

Summary of preventive treatment.—While for purposes of investigation it is better not to combine different therapeutic agents, since the specific effect of any one of them is thereby left in doubt, we are inclined in practice to recommend the use of all means that have any proven value.

As the first step, however, a careful review of all factors that may have led to previous abortions is desirable. Careful examination of the

abortion products often point to the cause. The absence of an embryo, evidence of a missed abortion (one retained a month or more after fetal death), or an imperfectly developed decidual layer, point to endocrine factors. Basal metabolism tests, the determination of sugar tolerance, and Wassermann reactions on both husband and wife give additional information. Pelvic examination reveals the presence of fibroids, retroversion and deep cervical tears. A careful check of the husband's spermatic fluid must be made. All these are included under the head of preconceptional diagnosis and appropriate corrective treatment is instituted.

After conception we would still hold to a maximum of rest and sedative, particularly at the time of the expected menstrual wave. How far to go in this direction is a matter of individual choice, but certainly in the presence of bleeding or cramps, indicating a threatened abortion, absolute bedrest is essential. More debatable is the value of opiates under such circumstances. There is considerable evidence, as recently shown in the experiments of Falls, Lachner and Krohn,[5] that morphine in ordinary doses may stimulate rather than inhibit uterine contractions. If morphine is used at all, not less than one-third grain hypodermically should be given. Recently I have been more inclined to use barbiturates, since the combination of bedrest and opiates leads to constipation that in turn promotes intestinal, and hence uterine, peristalsis. Whenever possible, a case of threatened abortion should be handled in a hospital where absolute rest can be secured, away from the petty annoyances of the home.

And now a few words more about the technic of endocrine treatment. Unfortunately the manufacture and standardization of progesterone is an expensive process and we are faced by the practical problem of meeting the drug bills. If it is true, as claimed by Bishop Cook and Hampson,[2] that less than thirty rabbit units are probably insufficient, it means that the use of this product alone will cost not less than $30. Pratt[16] believes that the human female does not require as large an amount of progesterone as the rabbit to inhibit abortion. Kane[6] prescribes 1/25 rat unit of proluton every other day for ten doses, a series that is repeated every three weeks up to the end of the fourth month. Falls, Lachner and Krohn[5] give one rabbit unit twice daily in threatened abortion and prophylactically twice a week up to the thirty-second week. My own experience would favor the use of the larger amounts.

There seems to be no contraindication to using thyroid extract in combination with some preparation of progesterone. The dosage employed by Werbatus[25] seems unduly high. He recommends one and a half grains three times daily up to four and a half months, and two grains three times daily thereafter up to the eighth month. I should feel it safer to use only one-half grain three times daily as suggested by Kane except in cases with persistent low basal rates. On the other hand some patients may require iodides to reduce thyroid activity. Thirty years ago habitual abortion was routinely treated by the administration of iodides and the occasional successes explained on the basis of a latent syphilis.

Vitamin therapy if carried out to the point recommended by Vogt-Möller, Shute and other enthusiasts is also very expensive. The wheat germ oil, used in Vitamin E treatment, must be given in large amounts. Shute uses 24 grains of such a preparation in the first twenty-four hours to produce the proper proteolytic reaction of the blood serum and four grains daily thereafter for the following months to keep it in that condition and so prevent abortion.

To summarize, then, in cases of spontaneous abortion, not due to lues, focal infection or gynecologic disease, I would employ a combination of progesterone, thyroid, Vitamin E, rest and sedatives. There is good reason to believe that such a combination, if carried out consistently for the first six months of gestation, will prevent almost every abortion except where there exists a primary defective germ-plasm.

Induced Abortion

We turn now to a consideration of the induced abortions and separate the legally from the illegally interrupted cases. In cases of hyperemesis, tuberculosis and certain forms of heart disease, therapeutic or legal abortion is resorted to less frequently than formerly, since our treatment of these conditions during pregnancy has shown material progress. The administration of intravenous glucose in hyperemesis has greatly reduced the number of serious toxemias that formerly required intervention. In tuberculosis the establishment of sanatorium treatment for pregnant women has lessened complications necessitating abortion. Fewer cases of

heart disease are interrupted nowadays, since the prevention of decompensation is better understood. On the other hand we have realized during these decades that in an increasing number of cases of mental and nervous diseases, of moral irresponsibility and of marked physical depletion, a therapeutic abortion may be advisable to conserve the best interests of the family as a whole both from a health and eugenic standpoint. In most of these cases, while there may be argument as to the legal right to interrupt the pregnancy, there is no question as to the desirability of preventing conception. The incidence of therapeutically induced abortion can be reduced to a minimum by widespread carefully supervised instruction in contraception and by prompt sterilization of the individual where this is definitely indicated.

The illegally induced abortions, greatest in number, present our most difficult problem. Here again we must turn to a thorough study of underlying contributory factors to get some clew as to the best methods of prevention. In few countries outside of Russia has any attempt been made to analyze these causes, and Russian conditions are so different from our own that little assistance is gained from studying their reports. From a large series of thousands of women questioned in the abortion clinics of Russia as to the reason for desiring interruption of pregnancy the following report[20] may serve as a fair cross-section: poverty, 44 per cent; illegitimacy, 11 per cent; too many children, 12 per cent; unhappy married life, 9 per cent; fear of confinement, 4 per cent; medical reasons, 13 per cent; other reasons, 7 per cent. Poverty and large families, therefore, account for over half of the cases.

A clinical and social study of abortion was recently made by H. S. Pasmore[14] analyzing 117 criminal abortions that came to St. Mary Abbot's Hospital, London. Unfortunately methods of induction employed and the use of contraceptives in these cases are given more attenthan analysis of the reasons for desiring the abortion. He found that religion apparently played no part, for the proportion of Catholics in this series was identical with the average for the population in that district. Abortion was relatively more frequent among illegitimate mothers. Another interesting study, published this year by R. Pearl,[15] deals with fertility and contraception among 7,500 white and negro women in New York and Chicago. One out of eight of these women had at least one induced abortion. They were "deliberately causing from 1/6 to more than 1/5 of their aggregate reproductive wastage by the dangerous expedient of induced abortion." Pearl stresses the fact that these abortions occurred twice as frequently among those women who practiced contraception than among those that did not, and adds the comment: "The abortionist is called on to rectify the inadequacies of birth control." Her report does not, however, justify the assumption that the practice of birth control leads to the practice of induced abortion, since it is self-evident that women who were anxious at all costs to avoid having another child would almost without exception practice some form of birth control, and conversely that women who do not practice birth control usually accept with resignation the occurrence of a pregnancy and less frequently resort to abortion.

In Dr. Kopp's[7] analysis of 11,172 abortions in New York City, the number of induced cases increased directly with the number of children in the family. As evidence of increasing poverty in these larger families she noted that more of them were done by midwives, or were self-induced. The 1934 Children's Bureau report on maternal mortality[24] pointed out that although abortion was relatively more frequent among unmarried mothers (one in three as compared with one in five), 90 per cent of all who died from abortion were married women.

The causes of induced abortion may then be summarized as due to: Poverty; large families; domestic troubles; illegitimacy; and selfishness.

It would be a Utopian dream to attempt to eliminate all these evils. All we can hope for is to reduce their extent to some degree. Poverty will be with us for centuries to come, but even the poorest countries, such as Russia, have in recent years taken steps to provide free hospital care and medical service for expectant mothers so as to lessen the hardship of childbearing. Surely it is the function of the state to provide maternal and child welfare and when such a program is carried out on a nation-wide scale it should materially reduce the temptation to resort to abortion. In addition, when the family gets beyond the three or four for whom the average parents can provide proper sustenance, our efforts should be directed along the line of

contraceptive education. We have only in the last two decades begun scientific research as to more certain and simpler methods of contraception and it seems not unlikely that these efforts will in the coming generation be rewarded by the discovery of measures that even the most dull-witted couple can employ with safety. When we have thus learned to limit the size of the family, the necessity for induced abortion should be reduced to a minimum.

Domestic troubles are largely dependent on poverty and too many children. When expectant mothers are deserted, the state should render financial and medical assistance if conditions require it. I do not wish to infer that the state should assume the full burden, but at any rate some help should be rendered to lessen the temptation to do away with the pregnancy.

The desire of the unmarried mother to induce an abortion is largely dependent upon our social code. How far this code should be modified to lessen the social ostracism now existing is for the coming generation to decide. If these foolish or unfortunate women were given a fair chance to earn a living for themselves and their child, more mothers would be inclined to carry on with their gestation and thus avoid the serious risks entailed upon instrumental interference.

Finally there is a large group of women who resort to induced abortions for no good reason except their personal convenience. Selfishness is an inherent trait in many of these women. The best corrective in these cases is to prove to them that for selfish reasons they would do better to carry their pregnancy to term. What these women do not appreciate is that every abortion carries with it a greater physical risk than a confinement, that the death-rate is seven times as great and that the resulting ill-health is probably ten to fifteen times as great. I am constantly impressed in private practice with the dense ignorance of intelligent women on this subject. Ten minutes of careful explanation will often make them change their plans and I know of no patients who are afterwards more grateful to their doctor for having saved them from taking such a false step.

I have left for the last the discussion of legal measures to control induced abortion. Since time immemorial the world has tried to limit this evil by punitive measures and utterly failed to accomplish anything except to increase the incidence of secret and more dangerous methods of interrupting pregnancy. I do not wish to infer that abortion should be legalized but I am convinced that punitive measures are a last resort and should be primarily directed against those individuals who make a profitable business out of its practice, those professional abortionists who through subterranean channels and paid agents induce women to resort to it as the easy way out. I notice that here in the State of Minnesota[12] you have recently caused the imprisonment of two midwife abortionists. As in other forms of crime, punishment of the criminal may be necessary but it is far less effective in producing results than a study of the cause of such crimes and their correction.

I am convinced therefore that the best results in reducing the incidence of criminal abortion can be obtained by:

1. More generous provision for the economic support and medical care of the expectant mothers among the poor.

2. Widespread information, especially among the poor, regarding the contraceptive methods that are at present available.

3. Intensive scientific investigation to discover safer and simpler methods of contraceptive practice.

4. An open discussion of this subject by both laity and profession so that the inherent dangers to life and health of the mother through induced abortion will be fully appreciated. Only in this way will the public appreciate the importance of preventing the decimating of the lives of expectant mothers and take the necessary steps for more effective control of the problem.

POLIOMYELITIS IN MINNESOTA IN 1937*

JOHN F. POHL, M.D.

Minneapolis, Minnesota

ACCOUNTS of poliomyelitis occurring in Minnesota are available for many years. During the thirty-year period from 1908 to 1938 there have been 7,927 reported cases of the diseases in the State. The statistical history of poliomyelitis is punctuated by a considerable fluctuation in the year by year incidence of the disease, but, however variable, in no twelve-month period has the abrupt increase over the thirty-seven cases reported for 1936, this number is not significantly above the average yearly expected level. It would appear (Table I) that the disease has not been very active in recent years.

Although the term is not well defined, there has been nothing in the nature of an epidemic in Minnesota since the year 1931. An aggregate of

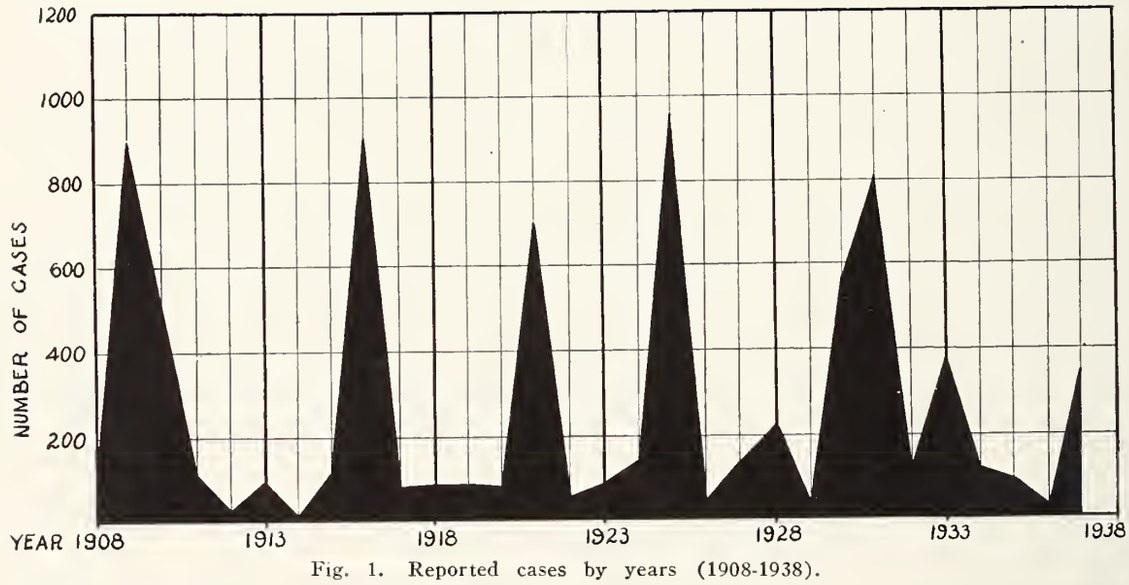

Fig. 1. Reported cases by years (1908-1938).

disease failed to make its appearance. An inspection of the charted course of poliomyelitis in Minnesota during the past thirty years (Fig. 1) indicates that there is a fairly sustained expected annual level of appearance of the disease, but that significant increases in incidence appear at fairly regular intervals.

The year 1937, with 354 reported cases, cannot be considered as unusual. Although a rather the cases by ten-year periods (Table II), however, gives no indication that the disease shows any tendency toward spontaneous recession.

There have occurred 1,421 deaths attributable to poliomyelitis in Minnesota during this thirty-year period. This is an average mortality rate of 17.9 per cent. Although great advances have been made in medicine during this time, very little has actually proven of benefit either in the prevention or treatment of poliomyelitis. By ten-year periods (Table II) there has apparently been a significant decrease in the mortality rate of the

*The figures used were obtained from the Division of Preventable Diseases of the Minnesota Department of Health, through the courtesy of Dr. Orianna McDaniel, Director of the Division, and her staff. The paper does not represent any official report of the Department.

TABLE I. CASES AND MORTALITY BY YEARS

Year	Cases	Deaths	Mortality
1908	150	9	6.0%
1909	900	234	26.0%
1910	481	201	41.8%
1911	115	58	50.4%
1912	35	23	65.7%
1913	85	30	35.3%
1914	22	8	36.3%
1915	123	26	21.0%
1916	912	105	11.5%
1917	75	10	13.3%
1918	82	22	26.8%
1919	85	16	18.8%
1920	80	18	22.5%
1921	702	102	14.5%
1922	55	20	36.4%
1923	82	17	20.7%
1924	144	30	20.8%
1925	955	145	15.2%
1926	46	15	32.6%
1927	139	36	26.0%
1928	224	57	25.4%z
1929	32	6	18.7%
1930	479	37	7.7%
1931	811	66	8.1%
1932	124	10	8.1%
1933	383	37	9.1%
1934	113	21	18.5%
1935	99	10	10.1%
1936	37	4	10.8%
1937	354	48	13.5%
Total	7927	1421	17.9%

disease. This might offer some hope that there is a tendency either toward a decreasing virulence of the causative agent or an increasing toleration by the host. It must be kept in mind, however, that these are only statistics. Considerable doubt must arise in regard to the diagnosis of poliomyelitis made twenty-five or thirty years ago. It is only comparatively recently that the technic of examination of the spinal fluid has reached a stage of refinement where an unquestioned diagnosis can be ascertained. In 1937, there were forty-eight deaths, a mortality rate of 13.5 per cent. This is slightly above the average rate for the ten-year period which the year concludes.

TABLE II. MORTALITY BY TEN YEAR PERIODS

Year	Cases	Deaths	Mortality
1908-18	2898	704	24.3%
1918-28	2370	421	17.8%
1928-38	2659	296	11.1%
Total	7927	1421	17.9%

TABLE III. CASES BY MONTH BY ONSET OF SYMPTOMS, 1937

Month	Jan.	Feb.	Mar.	Apr.	May	June
Cases	3	1	1	1	0	1
Month	July	Aug.	Sept.	Oct.	Nov.	Dec.
Cases	13	64	173	71	18	8

The year 1937 demonstrated strikingly one of the typical features of the disease, marked seasonal variation of incidence (Fig. 2). Throughout the entire first half of the year only seven scattered cases were reported. In July there began an abrupt increase which mounted to almost epidemic proportions through August and reached its peak in mid-September. The four months of July, August, September and October accounted for 321, or approximately 91 per cent of the total 354 cases for the year. About half of the total number of cases for the year appeared in the single month of September.

The disease was proceeding with considerable acceleration in 1937 when the schools opened on September 7. This incident was attended by no noticeable increase in the rate of appearance of new cases which might be anticipated as a result of the segregation of large numbers of potentially infected children. On the contrary the apparent epidemic reached its peak within the week thereafter, and each succeeding week saw a

progressive diminution in the number of new cases being reported. A few cases, however, continued to appear up to the close of the year (Table III).

peak of incidence appeared at approximately six years of age (Figure 3). By sex there was a preponderance of males, being 213 to 141 females.

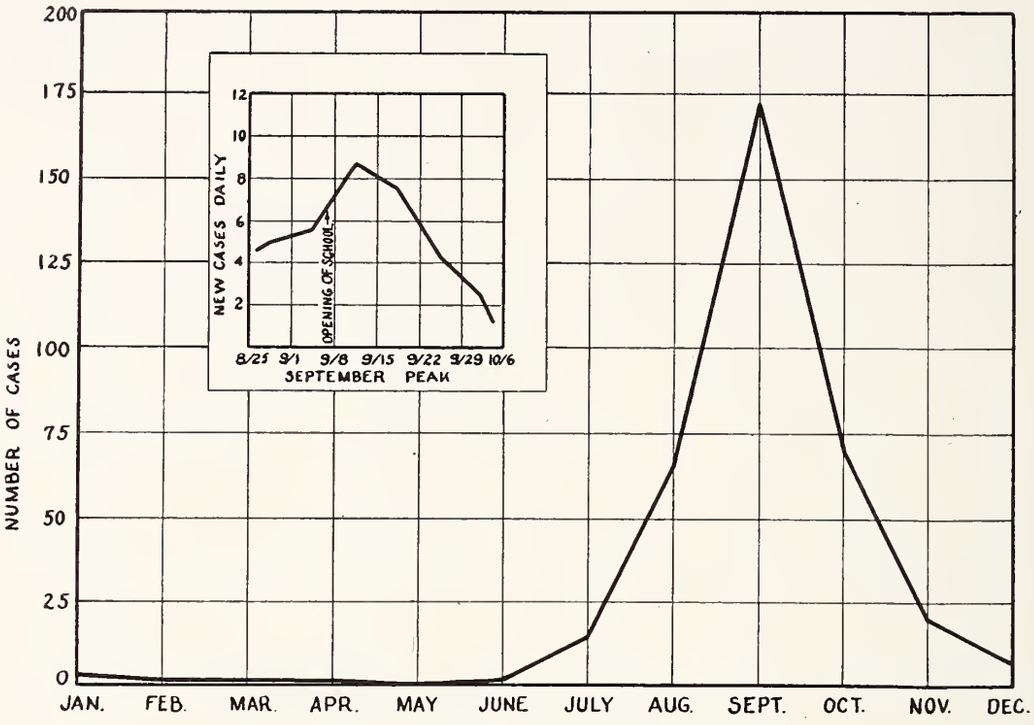

Fig. 2. Cases by month, by onset of symptoms (1937).

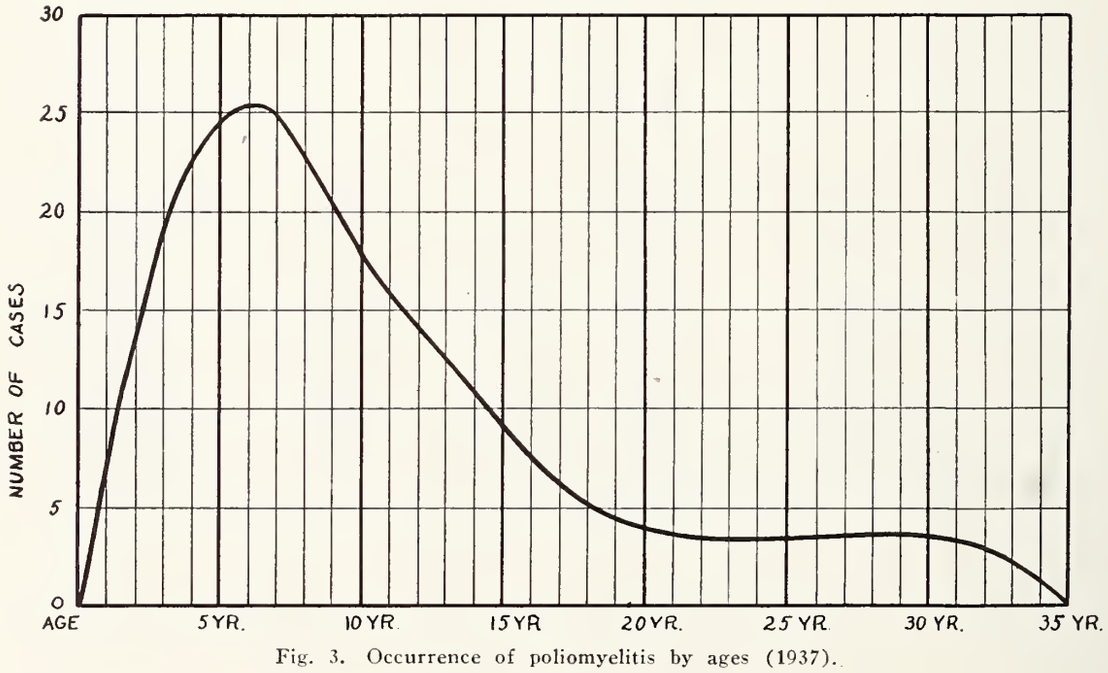

Fig. 3. Occurrence of poliomyelitis by ages (1937).

The majority of the individuals attacked in 1937 were between two and fifteen years of age, but there were victims in every year of life from birth to thirty-five. Three cases were reported in persons forty-four, forty-five and forty-eight years of age, respectively. The youngest child was six months of age, and there were three children under one year of age affected. The

Toleration of the infection varies considerably at different age levels (Table IV). The general mortality for 1937 was 13.5 per cent. Death did not claim any of the three infants under one year of age nor any of the three over thirty-five. The period of life between the ages of twenty and twenty-five appears to be the most vulnerable, having had, in 1937, a mortality rate of 31.6

per cent. No tabulation was made of the extent of paralysis at the different age levels.

Geographically, the cases in 1937 were fairly scattered in distribution, being reported from seven were of the abortive type, compared with only ten cases of the abortive type appearing in the 165 cases occurring throughout the State at large. It is logical to assume that more suspected

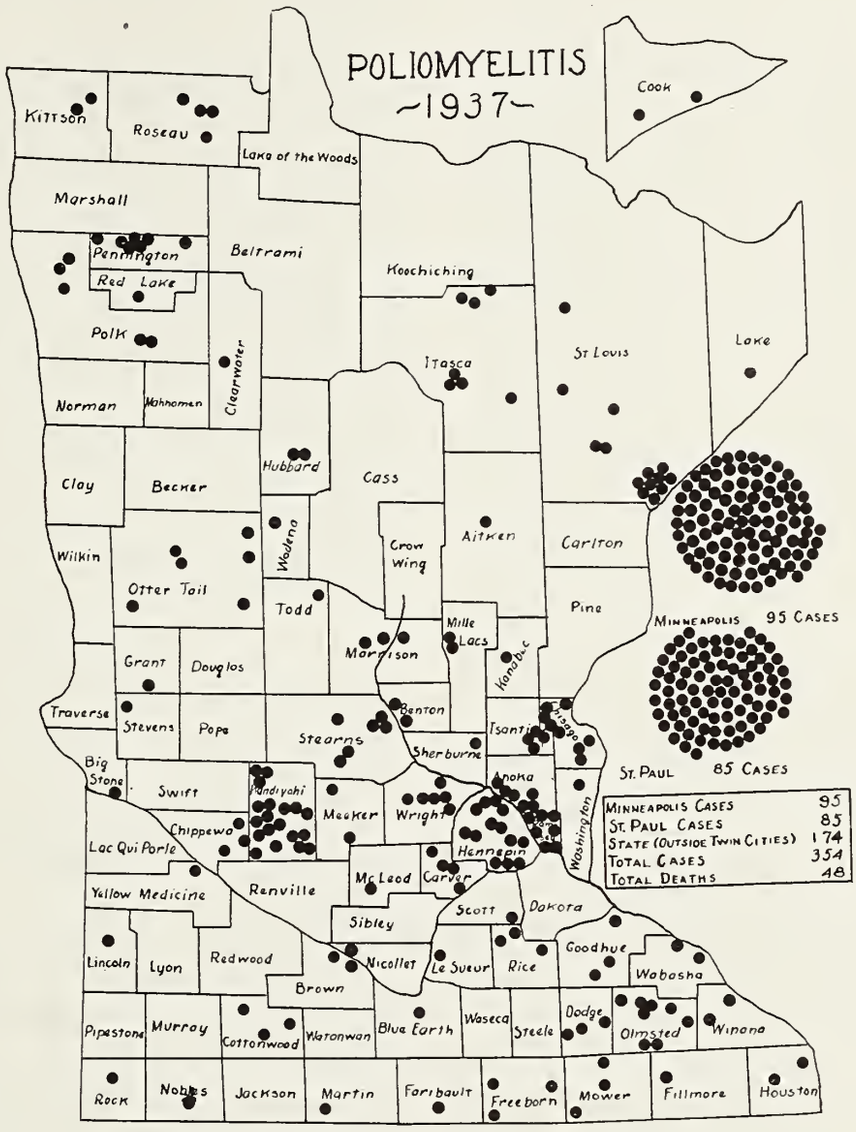

Fig. 4. Location of cases occurring in 1937.

fifty-six of the eighty-seven counties of the state (Fig. 4). The metropolitan districts of Minneapolis and Saint Paul, with a centralization of population, accounted for a good share of the cases. There were in addition minor centers of infection in other parts of the state, the principal one being in Kandiyohi County, from which twenty cases were reported.

The population of Minnesota (estimated 1934) is 2,602,000 people. The three largest cities, Minneapolis, Saint Paul and Duluth, comprise 32 per cent of the total population of the state. It appears that 189, or 56 per cent of the cases of poliomyelitis in 1937, were reported from these three centers of population. However, of the 189 cases occurring in these three cities, sixty-cases of poliomyelitis are hospitalized in the larger cities, where hospital care is more readily available. The inference from this assumption, and from the figures regarding the abortive type of poliomyelitis, is that the diagnosis of poliomyelitis is facilitated in direct proportion to the accessibility of hospital and laboratory aid. If one considers only the cases showing demonstrable muscle weakness or paralysis, it appears that the three areas of condensation of population (32 per cent of state population) accounted for 46.6 per cent of the cases of poliomyelitis reported for the year 1937.

The classification of abortive and paralytic types of cases as applied to poliomyelitis depends on the demonstration of objective neuro-

logic findings. The term paralytic is self-explanatory, indicating muscular weakness or paralysis. In addition, any patient showing depression of cutaneous or tendon reflexes, even though no measurable muscular weakness can be demonstrated, is also classified as paralytic. The abortive case is one having suggestive symptoms, the diagnosis of which, in the absence of peripheral neurological changes, is made usually by examination of the cerebrospinal fluid. Considering that only ten cases were diagnosed as the abortive type outside of the large city districts in 1937, it is a fair premise that many cases of poliomyelitis are overlooked each year. In many cases this situation is admittedly unavoidable. Given even a suggestive set of symptoms, with hospital facilities distant or unavailable, the diagnosis of acute anterior poliomyelitis is not easily made with assurance. In the city of Saint Paul in 1937, with eighty-five reported cases of the disease, 51 per cent were abortive in type. That is to say that an absolute diagnosis could be made in only half the cases without the aid of laboratory examination. For the three cities of Minneapolis, Saint Paul and Duluth, 36.4 per cent of the total cases were the abortive type.

TABLE IV. MORTALITY BY AGE GROUPS, 1937

Age	Cases	Deaths	Mortality
0- 5 yrs.	74	8	10.8%
5-10	101	11	10.9%
10-15	85	10	11.7%
15-20	40	7	17.5%
20-25	19	6	31.6%
25-30	16	3	18.8%
30-35	16	3	18.8%
Over 35	3	0	0.0%
Total	354	48	13.5%

With the greatest incidence of poliomyelitis occurring in the younger age groups it might be suspected that, as in the more common contagious diseases, there should be predictable increases in the occurrence of poliomyelitis at fairly regular intervals. The graphic record (Fig. 1) of the yearly incidence of the disease in Minnesota shows that this is borne out. Every five-year period from 1908 on has had one year with significant increase in the occurrence of the disease, except for the period just ended (Fig. 1). From these facts it would not be unexpected should there occur a considerable increase in the number of cases in the year or two immediately before us.

Summary

1. Statistics on acute anterior poliomyelitis in Minnesota are presented for the past thirty years.

2. During the past thirty years there has been no tendency for poliomyelitis to disappear in Minnesota.

3. There is a suggestion that the virulence of the causative agent is subsiding, or that man is developing a toleration for the disease. The difficulties in diagnosis, however, makes caution imperative in the interpretation of statistics.

4. The year 1937 showed only a moderate increase in the average annual level of incidence of the disease in Minnesota. There was a slight increase in the mortality rate above the level of preceding years.

Thiamin Chloride and Nicotinic Acid in Pellagra

Spies and Aring (J.A.M.A., April 2, 1938, p. 1081) report on the effect of the administration of vitamin B_1 in six cases of classic pellagra with peripheral neuritis. Irrespective of the cause of the pellagra, prompt relief of spontaneous neuritic pain resulted from the intravenous injection of thiamin chloride (crystalline vitamin B_1 hydrochloride). These observations suggest that vitamin B_1 deficiency plays a part in the development of clinical manifestations of peripheral neuritis associated with pellagra. The vitamin B_1 does not appear to cure the glossitis and stomatitis of pellagra but nicotinic acid, which has been referred to in *The Journal A.M.A.* (Jan. 22, 1938, p. 289; Feb. 26, 1938, p. 622), does relieve these symptoms. The Cincinnati investigators have demonstrated that all types of pellagra are benefited within twenty-four to forty-eight hours after the administration of nicotinic acid. Certainly both thiamin chloride and nicotinic acid deserve further intensive study in their relation to pellagra. (J.A.M.A., April 2, 1938, p. 1115.)

SACRAL BLOCK ANESTHESIA*

A Consideration of the Unusual Difficulties Encountered and a Report of Two Unusual Cases

R. CHARLES ADAMS, M.D., and EDWARD B. TUOHY, M.D., M.S. (Anes.)

Rochester, Minnesota

BY blocking the sacral nerves, anesthesia is produced which permits operations on the rectum, anus, urinary bladder, prostate, and perineum. Sacral block consists of a combination of caudal and transsacral block. By injecting only the caudal canal, complete anesthesia may be obtained in about 60 per cent of cases, using between 30 and 40 c.c. of a solution of 1 per cent procaine or metycaine. High caudal[1] block is a variation of caudal block in which larger quantities of the anesthetic solution are injected into the caudal canal and the resultant anesthesia obtained amounts to a peridural anesthesia from below upward. The extent of the anesthesia depends largely on the amount of the anesthetic solution injected which determines the height to which the solution rises. The amount of solution used varies from 40 to 90 c.c. and it is necessary to wait thirty minutes or more after injection to obtain complete anesthesia.

Ordinary caudal block must be supplemented in about 40 per cent of cases by transsacral block, in order to obtain complete anesthesia. This consists in blocking the second, third, and fourth sacral nerves bilaterally; occasionally it may be necessary to block the first sacral nerves as well. By combining caudal block with a bilateral block of the second sacral nerves, complete anesthesia may be obtained in about 80 per cent of cases. It is necessary, in all cases, to wait at least twenty minutes after injection to allow the oncoming anesthesia to become complete. For operations on the anus and on adjacent structures sacral block gives the following desirable features: (1) complete anesthesia, (2) complete relaxation, (3) anesthesia of the immediate field of operation only, (4) avoidance of certain systemic effects which frequently are associated with low spinal anesthesia, (5) systemic conditions which contraindicate both spinal and general anesthesia normally do not contraindicate use of sacral block, and (6) the anesthesia produced usually is of sufficient duration to permit the performance of the longest surgical procedures in the region.

The contraindications to the method are few: (1) infection in the region through which the needles must pass, such as infected pilonidal cysts and abscesses, owing to the danger of disseminating the infection, (2) idiosyncrasy to the anesthetic solution or to the vasoconstricting agent used in this solution, and (3) very nervous and hypersensitive patients.

Lundy's paper is a very detailed and complete treatise on the subject of the technic of sacral block. Only a few of the important steps of the method need be reviewed here. The skin over the sacrum is painted widely with an antiseptic solution, such as tincture of metaphen 1:200 or merthiolate 1:1000. The region is then draped. A solution of either 1 per cent procaine or 1 per cent metycaine[3] may be employed for the injection. The solution of metycaine produces a more rapidly oncoming anesthesia of a somewhat longer duration than procaine. Either solution gives satisfactory results. To 100 c.c. of the anesthetic solution, 1 c.c. of a solution of epinephrine (1:2600) is added. The addition of the epinephrine is essential if the anesthesia is to be of prolonged duration. At the time of injection, the solution should be warm, because a cold solution does not penetrate readily the nerve fibers. A solution which transmits a comfortably warm sensation to the volar surface of the forearm is of a correct temperature.

Before any wheals are raised or any injections are made, the position of the sacral hiatus and sacral foramina should be estimated and a drop of the anesthetic solution placed over the position of each. By so doing, the symmetry or asymmetry of the foramina in relation to the sacral hiatus becomes apparent. This preliminary step becomes very important when abnormalities of the bony sacrum exist. By its relation to the tip of the coccyx and to the sacral cornua, the position of the sacral hiatus is determined, the caudal needle is inserted and 20 c.c. of the anesthetic solution is injected very slowly. Before any solution is injected, frequent aspiration should be made with the bevel of the caudal

*From the Section on Anesthesia, The Mayo Clinic, Rochester, Minnesota.

needle in both anterior and posterior positions.

The dangers and effects caused by faulty position of the needles will be considered separately. The fluid should enter the caudal canal without resistance. The caudal needle is left in place until anesthesia has become complete. The transsacral portion of the block then is performed. Having identified the posterior superior spine, a point is taken one finger's breadth medial and inferior to it; this point is marked by a drop of solution. This corresponds on each side to the second sacral foramen. One finger's breadth below this point will be over the third sacral foramen and one finger's breadth below this, over the fourth. The position of the sacral hiatus will be found one finger's breadth below the fourth sacral foramen, medially. Should injection of the first sacral foramen be required, it will be found approximately one finger's breadth medial and superior to the posterior superior spine of the ilium. Wheals are raised over these points from below upward. The needles are inserted and the solution is injected. The amount required is usually 2 c.c. in the fourth, 3 c.c. in the third, and 10 c.c. in the second foramina. The foramina of the opposite side then are injected and, finally, in addition, 10 c.c. are deposited in the caudal canal. This brings the total amount of solution used to 60 c.c. If for any reason anesthesia is incomplete, a like amount may be used if required; this still will be within a safe limit of dosage.

Following completion of the block, the patient should not be tested for the presence of anesthesia for at least fifteen to twenty minutes. The testing should be done gently at first with the point of a needle on the skin posterior to the posterior margin of the anus. As the portion anterior to the margin of the anus is the last to become anesthetized, it should be tested last. If pressure with the needle occasions no discomfort, the same procedure is repeated with a tooth forceps. If the patient feels no pain, anesthesia may be considered complete. The presence of complete relaxation of the anal sphincter also should be noted. If an apprehensive patient is tested while the region is still sensitive, severe pain may be occasioned and this will lead the patient to interpret subsequent stimuli as painful, even after complete anesthesia has been obtained. The needles should not be removed until the anesthetist is assured that anesthesia is complete. The expected duration of the anesthesia is from one to two hours.

Conditions Affecting Sacral Block Anesthesia

Sacral block is a procedure which requires considerable experience and skill in order to obtain uniformly good results, but with the average case the experienced anesthetist encounters little difficulty. On the other hand, cases are encountered continually which vary from the average, normal case and these complications may be owing to a variety of causes. In such cases, the actual technic of performing the block becomes more difficult and anesthesia is more difficult to obtain. The latter section of this discussion will deal with the difficulties that may be encountered in abnormal cases and the various methods of handling such cases.

Conditions giving rise to these difficulties may be classified as follows: (1) faulty position of the patient during injection; (2) faulty position of the various needles; (3) extremely nervous and apprehensive patients; (4) abnormalities of the bony pelvis, such as differences between the male and female pelvis, previous injuries to the bones causing distortion of the landmarks and asymmetry, and osseous deposits in the foramina; (5) abnormalities of the soft parts, such as excessive subcutaneous fat, infection over the region of injection, and formation of scars distorting the soft parts, and (6) idiosyncrasies to the solutions employed, such as sensitivity to the anesthetic solution and sensitivity to the vasoconstricting agent.

Faulty position of the patient.—The correct position of a patient for sacral block is the prone position with the arms extended, the elbows semiflexed, the palms of the hands flat, and the head turned to the side opposite the one being injected. Two small flat pillows are placed under the pelvis and the sacral rest is elevated moderately. The patient is instructed to assume a "pigeon-toed" position (toes together and heels apart). This position makes the bony points of the posterior part of the sacrum more prominent and relaxes the muscles overlying them. The patient also is instructed to relax the muscles in that region as much as possible.

Faulty position of the needles.—The caudal needle in place in the caudal canal of the male will lie more nearly parallel with the horizontal plane of the body (when the patient is in the

prone position) than when in the caudal canal of the female because of the greater degree of pelvic curvature of the latter. If this point is not remembered, it is easy to pass the caudal needle over the posterior wall of the sacrum. The bone always should be touched with the point of the needle, both anteriorly and posteriorly. When injecting the caudal canal, the palm of the hand should be placed over the sacrum so that any extravasation of fluid in that region will be appreciated. Frequent aspirations should be made before any solution is injected in order to make certain that the point of the needle is neither in a vein nor within the dura. If the point of the needle is kept below the level of the second lumbar vertebra there is little danger of this taking place. When there is any doubt regarding the aspiration of spinal fluid, the point of the needle should be withdrawn until no further aspiration can be made. In certain cases it is possible to aspirate a straw-colored cystic fluid on introduction of the caudal needle. In these cases, it is preferable to do a low spinal block, although the aspirated fluid obviously is not spinal fluid. When the bevel of the caudal needle has scraped the bony wall of the caudal canal, a hematoma may be formed and blood may be aspirated. This will also occur if the point of the needle has been introduced into a vein. In cases of carcinoma of the rectum particularly, the venous plexus within the canal seems to be very extensive. If aspiration of blood continues to occur with the point of the needle in various situations, this part of the injection should be delayed until the remainder of the block has been completed. This gives a chance for bleeding to cease. Even after bleeding has ceased, the injection into the caudal canal should be made with caution, because under such circumstances the solution may be absorbed more rapidly than normally into the circulation. When the aspiration of blood persists, the caudal injection should be withheld and the transsacral part of the block should be depended on for anesthesia.

The needles, when inserted correctly into the foramina, will be roughly at right angles to the caudal needle. In inserting these needles, no great amount of force should be used, especially if bone is encountered. The shaft of the needle should not be bent during the insertion. These errors easily may result in the breaking off of part of the needle under the skin. The wheals should be raised slightly lateral to the foramen so that, before the needle is inserted, the skin may be pushed medially. This allows freedom of movement of the skin and subcutaneous tissue when inserting needles in the opposite side and prevents force being transmitted to those needles already in place. It is important that the point of the needle be inserted a distance of only a half finger's breadth into the foramen. If inserted too far the anesthetic solution will be extravasated anteriorly and will not reach the nerves.

Nervous patients.—Most patients tolerate the injection well if they are told what is about to happen and if injection of solution is made ahead of the needle, as the needle is being inserted through the tissues. A few patients are extremely intolerant. In many of these cases, if the injection can be made into the caudal canal and this injection allowed to take effect before the remainder of the block is attempted, the resultant anesthesia obtained may make the transsacral portion of the block bearable. Much apprehension may be combated by adequate premedication with morphine and pentobarbital sodium. Rarely is a patient so intolerant that his movements cause a needle to be broken. In such cases, it may be preferable to carry out the operation under intravenous anesthesia with pentothal sodium.

Abnormalities of the bony pelvis.—Differences between the male and female pelvis are the first consideration. The female pelvis is broader and the sacrum is more curved than that of the male. This results in some variation in the position of the needles both in the foramina and in the caudal canal. The fact that the male sacrum is more flat causes the caudal needle, when correctly inserted, to lie almost parallel with the horizontal plane of the body when the body is in the prone position. The curvature of the sacrum of the female results in the caudal needle pointing upward and more forward when in position, thus increasing the angle between the shaft of the needle and the horizontal plane of the body when the body is in the prone position. This feature must be borne in mind when inserting the caudal needle when treating women, for, if the plane of insertion of the needle is too flat, it may pass upward over the posterior surface of the sacrum instead of entering the canal itself.

The posterior superior spines of the female pelvis are farther from the midline than those of the male, because of the increased breadth of the former over the latter. As the second sacral foramen bears a constant relationship to the posterior superior spine, the imaginary lines passing through the two rows of needles inserted in the foramina of each side of a female pelvis will have a greater divergence from below upward than such lines passing through needles so placed in the male pelvis. In the latter, the two rows of needles will be more nearly parallel.

Injury and displacement of the bones are the second consideration. Old fractures involving the pelvis and the sacrum may result in varying degrees of displacement of the bones in whole or in part with accompanying distortion of the bony landmarks. Other factors leading to a similar condition may be congenital displacement or previous operations in the region. The coccyx itself may be displaced or absent. Although the sacral cornua usually can be palpated, among certain patients, particularly among the obese, definite prominences cannot be felt. Although the posterior superior spine on one side is usually symmetrical with that of the opposite side, some cases present wide discrepancies. However, even after injury to the sacrum there is usually a symmetrical relationship between the posterior superior spine and the second foramen of the same side and, also, between the foramina themselves. For these reasons, it is erroneous to use the needle inserted in the foramen on one side as a guide for inserting those on the other side.

Osseous deposits in the foramina are the third consideration. When inserting the needles in the foramina, only light pressure should be applied and, as the needle passes inward, this pressure should be decreased. Marked resistance usually indicates that the point of the needle is on bone and excessive pressure may result in breaking the tip of the needle or in hooking the point. Among some elderly patients, the foramina may be ossified partially or completely, leaving a small opening or none at all. In such cases, a cautious increase in pressure may be required to insert the needle. Undue movement of the patient's hips when the needles are in place also may result in breaking the shaft of a needle. During the injection of the anesthetic solution, the shaft of the needles must be supported. If a large portion of a needle breaks beneath the surface of the skin and cannot be recovered, it will be preferable to incise the overlying skin and remove the needle at once. If only the point is missing, probably it will do little harm and will be better left alone.

Abnormalities of the soft parts.—Excessive subcutaneous fat is the first consideration. In the main, among obese patients there is greater difficulty in placing the needles correctly than among patients of average weight. In the latter, the bony landmarks usually may be seen as well as palpated. Increase in fat progressively masks these landmarks until none of them can be felt accurately. When such is the case, various digressions from the standard technic are necessary. The usual routine is to insert the caudal needle followed by those of the foramina. When none of the landmarks for inserting the caudal needle is palpable, the procedure should be reversed. Even among the most obese patients, a definite dimple in the skin will be evident overlying the region of the posterior superior spine. Using this as a landmark, one may locate the second, third, and fourth foramina on either side and insert the needles. The situation of those in the fourth foramen of either side then will serve as a guide to the location of the sacral hiatus. A needle 50 mm. in length may not be long enough to reach the foramina of such subjects and one 80 mm. in length should be used.

Infection in the region is the second consideration. One definite contraindication to sacral block is the presence of infection in the skin or subcutaneous tissue through which the needles must pass. Such conditions as infected pilonidal cysts, large abscesses or furunculosis of the skin, or infection from any cause make it advisable to perform a low spinal block or, possibly, to give an intravenous anesthetic. In the ordinary case, care must be taken to prevent introduction of infection, particularly from the region of the anus. The tip of the coccyx always should be palpated through a sterile towel. Multiple punctures by needles also increase the risk of infection. Occasionally, small pustules form at the site of the punctures because of careless technic.

Formation of scars is the third consideration. It is a frequent fault of beginners to be guided by the soft parts (gluteal cleft and midline) rather than by the bony landmarks. Such technic is

certain to give rise to error, as the relation of the soft parts to the bones may possess any degree of variation, particularly following accident and injury. Accidents occur resulting in injury to the region in which the bones are not affected, but the overlying soft tissue may be so lacerated that, in healing, the resultant formation of scars with contraction may distort the normal contour of the skin grossly. Scarring from infection or from suppuration of long standing also may result in similar deformities. Two abnormal cases to be described subsequently will serve to bear out these conclusions.

Idiosyncrasies to the solutions used.—A patient may be sensitive to the anesthetic solution, to the vasoconstricting agent, or to both. Reactions to anesthetic solutions are frequent. Careful questioning of the patient before the injection is made may reveal this. The vasoconstricting agent is necessary to obtain duration of anesthesia but many patients are sensitive to epinephrine, and, in such cases, it should be omitted or cobefrin should be substituted. The preliminary injection should be made very slowly and should be discontinued if signs of hypersensitivity appear. Similar effects may result if the injection is made intravenously. Nausea and vomiting are complications which may occur. Inhalation of 90 per cent oxygen and 10 per cent carbon dioxide usually relieves these symptoms.

Case Reports

The following report of two abnormal cases is submitted in support of some of the previous statements.

Case 1.—A man, aged sixty-three years, weighed 140 pounds. Twenty years previous to his admission, he was run over by a wagon which weighed 4,300 pounds. One of the wheels passed over his pelvis. He was incapacitated for three weeks but was able to resume an active life about two months after the accident. Walking was not impaired. The reason for seeking medical attention at this time was because of increasing constipation and the passage of mucus and, recently, blood from the bowel. Examination revealed polypoid adenocarcinoma of the rectum, grade 1 (on the basis of 1 to 4), and hemorrhoids. The lesion was fulgurated under sacral anesthesia.

On examination of the sacral region at the time the sacral block was performed, gross bony abnormalities appeared to be present. The whole sacrum appeared to have been pushed to the right. However, the needles were inserted without difficulty and good anesthesia was obtained. Roentgenologic examination of the region did not reveal any distortion of the bones. The accompanying photograph (Fig. 1) in which the landmarks are indicated by markings with a colored solution, will give the reader a clear picture of what had happened. The two upper dots are over the posterior superior spines, the next three are over the second, third, and fourth sacral foramina of either side and the lower one represents the sacral hiatus. The midline of the skin has been extended upward from the gluteal cleft. The upper line marks the spinous processes of the lumbar vertebræ. The previous injury had torn the subcutaneous tissue so that the subsequent formation and contraction of scars which resulted had pulled the skin to the right, so that a line projected upward from the gluteal crest fell to the right of the right sacral foramina, giving the illusion that the bones had been distorted. This case shows the importance of relying solely on the bony landmarks.

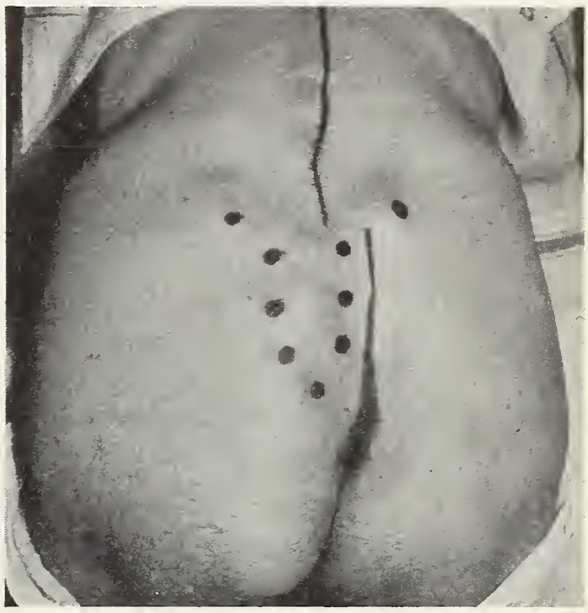

Fig. 1. Upper vertical line follows the alignment of the spines of the vertebræ; the lower line is a continuation upward from the gluteal cleft. The uppermost spot on each side overlies the right and left posterior superior spines, respectively; below them the pairs of three spots on each side overlie the second, third, and fourth sacral foramina, respectively. The lowest spot is the site of the sacral hiatus. Note how the skin overlying the sacrum has been pulled to the right by contracted fibrous tissue so that a continuation of the midline of the skin as extended upward from the gluteal cleft passes to the right of the sacral foramina on the right side.

Case 2.—A man, aged sixty-two years, had rectal trouble with an abscess near the rectum which began thirteen years previous to admission. Sinus tracts formed which periodically opened and closed, and at times new abscesses formed. Three operations had been performed in the past eleven years. In addition, his left leg had been run over thirty years previously. A stiff hip joint developed subsequently. On admission, the perirectal region contained many indurated masses, fistulous openings, and scars (Fig. 2). A sacral block was performed prior to operation and adequate anesthesia resulted. The prolonged suppuration and formation of sacral scars resulted in considerable distortion of the soft tissues as illustrated in Figures 3 and

Fig. 2. The condition of the region of the anus previous to operation; probes have been placed in the multiple sinus tracts.

Fig. 3. The relation of the caudal needle, inserted in the caudal canal, to the gluteal cleft.

Fig. 4. The relation of the needle in the caudal canal and those in the various foramina to the gluteal cleft and anal region.

4. Figure 3 is an illustration of the caudal needle in place in the caudal canal. Note how the gluteal cleft has been displaced to the left. Figure 4 is an illustration of all the needles in place; a line projected upward from the gluteal cleft, passes through a line joining the foramina on the left side.

Cases such as these are examples of the abnormalities which may occur in the region of the sacrum and how they may affect the performance of a successful sacral block. Sacral anesthesia has many advantages and few disadvantages. It supplies ideal operating conditions for the surgeon and involves a minimal risk to the patient.

DIAPHRAGMATIC HERNIA*

E. MENDELSSOHN JONES, M.D.

Saint Paul, Minnesota

THE diagnosis and treatment of diaphragmatic hernia has received increasing attention during the past few years. There is no reason to assume the condition to be more prevalent than heretofore, but rather that improvement in diagnostic methods has made its presence more easily and thus more frequently proven. Development in roentgenological technic, together with accurate clinical observation, has resulted in the placing of diaphragmatic hernia in the list of commoner conditions. Too often in the past improper treatment has been due to failure in diagnosis. In obscure abdominal conditions the possibility of its existence must always be borne in mind.

In 1853 Bowditch reviewed the subject of diaphragmatic hernia and reported a case seen at the Massachusetts General Hospital, observing that earlier writers believed that a wound of the diaphragm was always fatal. He quotes Dr. Fothergell, whose letter to Dr. Mead about one hundred years before gives a very interesting account of a case of diaphragmatic hernia. Dr. Fothergell says, "Everyone skilled in medicine, I think, will suppose from the history that the disease was a new one. But who would ever have conjectured that the diaphragm was divided asunder and that a large portion of the stomach and intestines had rushed through the opening into the breast." A century and a half before this letter was written, two cases were reported in the Opera Chirurgica by Ambrose Paré. One of these proved the fallacy of the older writers in believing a wound of the diaphragm was always fatal.

Bowditch collected eighty-eight cases and stated that he had carefully examined many works and journals from 1610 to 1846, believing that few more could be found.

Harrington points out that the clinical study of proven cases has established a fairly definite symptomatology, very helpful in making a diag-

*Presidential address before the Minnesota Academy of Medicine, January 12, 1938.

nosis or at least suspecting the presence of a diaphragmatic hernia.

At the Mayo Clinic between 1900 and 1925, thirty cases were recognized, of which nineteen patients were operated upon. From 1925 to 1935, one hundred and ninety-seven cases were recognized with one hundred and five patients operated upon. Harrington further points out that the condition is more common than believed at present, as he has made examinations of the diaphragm during other abdominal operations and has occasionally found a small hernia which had not been recognized clinically or roentgenologically before operation.

Diaphragmatic herniæ are considered true or false depending on whether or not a sac is present. They are further divided into congenital and acquired, the latter possibly traumatic in origin. In this classification a congenital hernia is understood to have been present at birth, the absence of a sac indicating that the hernial opening was due to the failure of the development or fusion of one or more of the anlagen of the diaphragm. Occasionally a congenital hernia has a sac and this is evidence of hernia formation after the complete separation of the pleural and peritoneal cavities.

The acquired hernia develops after birth and usually has a sac. This type generally occurs at the esophageal opening, the para-sternal foramen, or the lumbo-costal trigone.

A traumatic hernia may be caused by direct or indirect injury or by inflammatory necrosis of the diaphragm. In a direct injury such as a gun shot or stab wound, the hernia may occur at any point. When the injury is due to an indirect influence such as a crushing chest injury, the most frequent location of the rupture is the dome and posterior half of the left hemi-diaphragm. This type of hernia usually has no sac. When the hernia occurs at the esophageal opening there is a sac present. If the injury to the diaphragm is caused by inflammatory necrosis, the opening in the diaphragm is usually posterior and there is no hernial sac.

The symptoms in these cases depend on the structures involved in the hernia. When the stomach is the only organ involved, a very different picture is presented from that in which the intestines, as well, are herniated through the diaphragmatic defect. The diagnosis is not infrequently missed because the symptoms presented are referable to the chest; shadows may be present on the roentgenogram readily simulating a number of other conditions. It will be seen, therefore, that the possibility of a diaphragmatic hernia should always be borne in mind during routine chest x-ray examinations.

Herniations of the fundus of the stomach may result in typical cases of hour-glass deformity, and, because of the altered blood supply of the diaphragm and traumatism following its constant movement, ulceration may result. In some cases malignant changes have been found. With accurate observation loops of bowel or portions of the stomach may be seen in the chest without the administration of barium, if the possibility of hernia is borne in mind. The freedom of fluid or gas in the bowel, or the presence of some pleural thickening, may so mask the picture that an incorrect diagnosis is made. Truesdale cites a case in which such an error in diagnosis was made and a quantity of milk was removed by exploratory thoracentesis. Downs cites cases with death resulting from exploratory thoracentesis. Many patients with these conditions have been classed as neurotics because of the vagueness of their symptoms.

The manifestations of diaphragmatic hernia are frequently very complex and simulate those of various other organic conditions in the abdomen and thorax. Not infrequently one or more incorrect diagnoses have been made in these patients before the presence of a diaphragmatic hernia is discovered. It has often been confused with gall-bladder disease, gastric or duodenal ulcers, hyperacidity, secondary anemia, cardiac disease, carcinoma of the cardia, stricture of the esophagus, appendicitis, or intestinal obstruction.

In the congenital hernia the symptoms are usually present immediately after birth or at least in the early weeks or months of life. Many of these patients die a few hours after birth from respiratory and circulatory failure. Truesdale points out that diaphragmatic hernia may be more common than suspected from mortality statistics. He feels that autopsies are done less frequently in children than in adults and without a post mortem examination there is always a possibility of an error in diagnosis.

Should an infant with a diaphragmatic hernia survive a few weeks, the chief symptoms are cyanosis and dyspnea, but as the child grows older these symptoms become milder and those of

a digestive disorder become more prominent. A patient with a congenital hernia living to adult life has an unusually fixed mediastinum. Such patients may be symptom-free, but when evidence of any disturbance does occur the picture is usually that of an intestinal obstruction.

Hiatus herniæ often cause considerable disturbance of respiration, circulation, and deglutition. In 1933, Junfer reported a case of an esophageal hiatus hernia in a man sixty-five years of age, the sac containing the stomach and most of the omentum. The esophagus measured only seventeen centimeters in length, and was believed to be a true esophageal hiatus hernia acquired early in life. The stomach had entered the chest early and since there was no traction on the esophagus, it remained short. It is readily understood that in this patient there had been no constriction of the stomach and the diaphragm maintained its normal rhythmic movements. In patients with a hiatus hernia with no other pathological complications the symptoms are fairly well understood, since more individuals of this type have been carefully studied. There is usually a sense of fullness in the substernal region and this is associated with substernal distress. Hiccough and heartburn are frequently present. If a large amount of food is taken just before retiring these symptoms are exaggerated. Relief is usually obtained by vomiting. Other cases may present epigastric fullness after meals. There is rarely a complaint of pain and the distress is substernal rather than epigastric.

The symptoms produced by traumatic hernia vary according to the viscera herniating through the diaphragmatic opening. As this type of hernia is without a sac there is usually a greater amount of abdominal contents passing into the thoracic cavity. When the opening is small, due to direct injury, such as a stab or gunshot wound, obviously only a small herniation can take place; in the indirect injury resulting from a severe blow or crushing chest injury, the hernial opening may be very large and the stomach, with most of the intestines, is frequently found in the chest. This is especially true if the diaphragmatic injury is on the left side. When it occurs on the right side the liver frequently is partially or wholly herniated through the opening and it is unusual to find any extensive herniation of the stomach and intestines.

In this type of a hernia the patient complains of abdominal cramps and considerable gastric distress, especially after eating. There may be respiratory distress evidenced by shortness of breath due to the pressure on the lung and mediastinum by the viscera in the pleural cavity. There may be constipation, and, when a laxative is taken, active peristalsis causes a gas rumbling in the chest which is audible to the patient. This is a very annoying symptom.

When one has this type of case under observation the possibility of an intestinal obstruction developing must be constantly borne in mind. Because of the general condition of cases that have had severe injury with resultant diaphragmatic hernia, it is frequently impossible to repair the hernia until the patient's condition improves.

The diagnosis of herniæ of the diaphragm has become much more frequent with the refined and exact roentgenological methods that are being used, and it is felt that x-ray demonstration is the only sure means of diagnosis. It has been pointed out that the x-ray is not infallible and not infrequently small herniæ are missed. Jenkinson and Roberts feel that less than five per cent of the small herniæ can be identified if the patient is examined only in the erect position. It is evident that close coöperation between the roentgenologist and the clinician is necessary as it is not uncommon to have these cases present a symptom-complex that is not understandable after the most searching examination, and as many of the conditions which cause symptoms referable particularly to the upper abdomen and chest simulate those presented by various types of diaphragmatic hernia, it is essential to keep this possibility in mind. This observation is applicable to the congenital, acquired, and traumatic types of hernia. In the traumatic cases the diagnosis should usually be rather simple, as the symptoms are more acute and the physical findings are much more definite. As pointed out, a good x-ray examination is most essential and this should be carried out in all cases that have had a direct or indirect injury of the chest. Any case that has had a crushing injury of the chest should have a complete gastro-intestinal examination, including a barium enema. If this routine is followed, most traumatic herniæ will be diagnosed. Pneumoperitoneum may be a helpful diagnostic aid in differentiating a diaphragmatic hernia from an eventration of the diaphragm.

Another condition that must be differentiated

from diaphragmatic hernia is the congenital short esophagus. In 1931, Findlay and Kelly discussed an anomaly that was characterized by congenital shortening of the esophagus and the presence of a portion of the stomach in the thoracic cavity. There was also a stenosis of the junction of the esophagus and thoracic portion of the stomach.

It is very important from a surgical standpoint to determine whether one is dealing with a shortening of the esophagus, with resulting partial or complete intrathoracic stomach, or whether there is a herniation of the stomach into the thoracic cavity.

One must also consider the possibility of the presence of a diaphragmatic hernia in cases of dextro-cardia.

Reduction of the hernia with repair of the hernial opening is the only means of definitely relieving the symptoms. There are undoubtedly many cases of diaphragmatic hernia that are symptom-free, and as long as strangulation does not occur the presence of abdominal viscera within the chest is not incompatible with life.

A most troublesome complication is that of intestinal obstruction, the mortality from intestinal obstruction being higher because of the necessity of the hernia repair. When the stomach is the only viscus involved, incarceration may occur and not strangulation, and the mortality is not as high. Truesdale advocates the employment of a two-stage operation to reduce the mortality occurring when dealing with cases complicated by intestinal obstruction. He advises first an appendicostomy or cecostomy to relieve the obstruction, the hernial repair being an operation of election.

In congenital hernia in infants the results of surgical repair have been disappointing, although some successful cases have been reported. The most favorable types are those passing through the left pleuroperitoneal canal, lateral defects in the septum, and small herniæ around the esophagus. The abdominal approach is preferred, as there are rarely any adhesions present. It is important to overcome the pneumothorax at the conclusion of the operation.

In discussion of the repair of the acquired type, the method of approach is dealt with in detail. Some surgeons prefer the thoracic operation while many prefer to use, when possible, the abdominal approach. If the hernia is on the right side, the thoracic approach is selected, since the liver interferes with adequate exposure, making the repair difficult.

Harrington thinks there is less risk of thoracic complications when the abdominal approach is used, and he uses this approach in all cases of hernia through the left hemi-diaphragm. He feels it is of particular advantage in cases of hernia through the esophageal opening, as the herniated stomach is usually confined in a sac in the posterior mediastinum and does not enter the true pleural cavity.

It is sometimes necessary to do a combined thoracic and abdominal operation as the viscera may be involved by adhesions which can not be freed from either abdominal or thoracic exposure alone.

Crushing of the phrenic nerve is frequently done in the traumatic herniæ that have a large opening, since the repair of an inactive diaphragm is easier. Crushing does not cause permanent injury to the nerve, and the diaphragm resumes its activity again in six to nine months.

I wish to present five cases of diaphragmatic hernia emphasizing some of the clinical manifestations that have been discussed.

Case 1.—A woman thirty-five years of age was first seen on February 25, 1935. She stated that she had suffered more or less upper abdominal distress for nineteen years. At that time she fell, striking the handle bars of a bicycle so severely that the bar was broken. She subsequently had severe pain in the abdomen and was ill in bed a number of days. Since that time she has had occasional spells of nausea and vomiting after meals. The vomiting has been more frequent during the past three years, occurring almost daily. The attacks never came before meals and were always worse when lying down.

The clinical impression was that of gall-bladder disease. An x-ray examination showed a non-functioning gallbladder but all relevant physical findings at that time were negative. In March, 1935, a gastro-intestinal tract x-ray study showed a herniation of the cardiac end of the stomach through the esophageal opening.

She was kept under observation on medical management, but since the symptoms did not subside it was felt that the diaphragmatic hernia was the cause of her disability.

After reducing her weight 15 pounds, an operation was performed on May 18, 1936. The roentgenologic findings were substantiated. The hernia was reduced and the esophageal opening, which readily admitted three fingers, was sutured. She made an uncomplicated recovery. A radiograph taken June 4, 1936, showed the hernia reduced and a picture on October 17, 1937, shows no recurrence. At present she is in good health and has complete relief of her symptoms.

Case 2.—A woman thirty-three years of age was first seen on October 18, 1935. She had been well until one year before, when she developed attacks of heartburn followed by nausea and vomiting. Occasionally she noted sharp epigastric pain radiating from the umbilicus to the epigastrium and the right scapular region. The pain was relieved by vomiting and deep breathing. She had had nausea during the last six weeks and vomiting had become more frequent.

Fig. 1. Case 1. Esophageal hiatus hernia.

Fig. 2. Case 1. Radiograph taken one and a half years after repair. No recurrence.

Fig. 3. Case 2. Shows esophageal hiatus hernia.

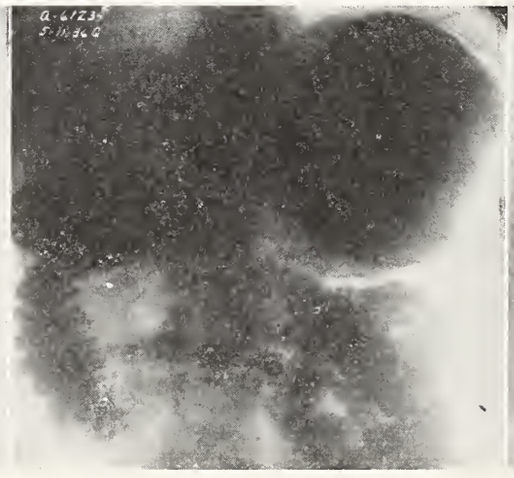

Fig. 4. Case 2. Radiograph taken three months after repair shows no recurrence.

Fig. 5. Case 2. Radiograph taken one and a half years after repair shows a recurrence.

The patient was markedly overweight. Disease of the gallbladder or peptic ulcer was suspected, but x-ray examination showed a normally functioning gallbladder and there was no evidence of a lesion of the stomach or duodenum. There was found, however, a slight herniation of the cardiac end of the stomach through the esophageal opening. The diaphragmatic hernia was thought to be the cause of her symptoms and an operation advised.

She was put on medical management, reducing her weight from 210 pounds to 165 pounds.

On April 25, 1936, she was operated upon. The hernia was repaired and she made a good recovery. X-ray examination in June, 1936, showed no evidence of the hernia. This patient was last seen in October, 1937, when her weight was found to have increased to 212 pounds. She stated that until June, 1937, she felt well and had had no return of the symptoms experienced before the operation in April, 1936. Since June, 1937, she has had attacks of smothering at night and at intervals a gnawing sensation in the substernal region. The intervals between attacks ranged from a few days to three or four weeks. X-ray examination in October, 1937, showed a recurrence of the hernia. If this condition progresses her weight should again be reduced and another repair undertaken.

Case 3.—A woman sixty-one years of age was first seen in May, 1937. She dated the onset of her illness by an attack of whooping cough which she contracted when a child. Since that time she had noted heartburn, nausea, occasionally associated with vomiting, and pain in the back and under the left costal margin occurring one to three hours after meals. She could not eat large quantities of food without vomiting, and during the past year she had marked dyspnea after meals. The symptoms were aggravated when lying down.

She consulted several physicians because of stomach trouble, and had been on an ulcer diet several times.

Each time the symptoms were aggravated. There was nothing of note on general examination. On x-ray examination the gallbladder was reported as normal, but the gastro-intestinal examinations showed an extensive herniation, through the esophageal opening, of the cardiac end of the stomach.

Fig. 6. Case 3. Large esophageal hiatus hernia.

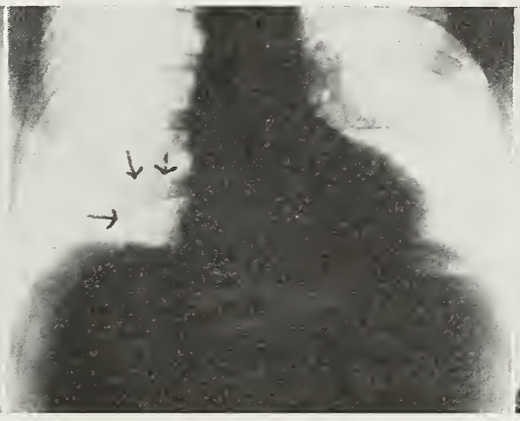

Fig. 7. Case 4. Herniation of colon through opening in right diaphragm.

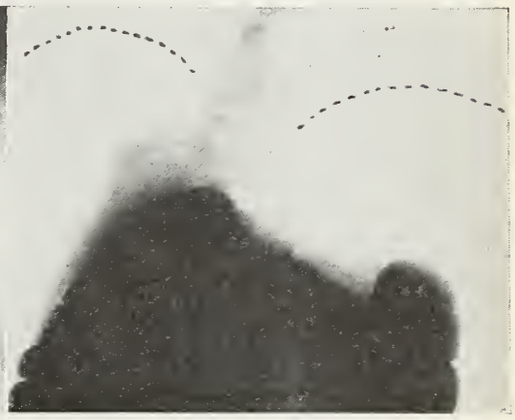

Fig. 8. Case 4. Barium enema one year after repair shows no recurrence.

On May 1, 1937, an operation was done for the repair of the hernia. The esophageal opening readily admitted three fingers. The immediate postoperative condition was satisfactory although her pulse rate was one hundred and forty. She was placed in an oxygen tent and stimulation was given. The day following the operation a blood transfusion was done and her condition improved. Forty-eight hours after the operation she had a sudden attack of dyspnea and cyanosis. A second transfusion was done but she continued to complain of dyspnea. Examination of the chest revealed no abnormalities. Later that day the patient appeared very alert and coöperating, but died suddenly following a short conversation with the nurse.

An autopsy revealed the cause of death to be multiple pulmonary emboli.

Case 4.—A man forty-three years of age was seen in June, 1935. He had been under treatment off and on since 1914 for duodenal ulcer. An x-ray study showed the presence of a duodenal ulcer with some pyloric obstruction. A gastro-enterostomy was advised and this was done in July, 1935. On opening the abdomen the liver and duodenal areas were obscured by the colon that ascended into the right thoracic cavity through an opening in the diaphragm. The opening was about 4 inches in length and there was a sac present. The colon was easily reduced as there were no adhesions between the colon and the hernial sac. The defect in the diaphragm was repaired. The duodenal ulcer was found and a posterior gastro-enterostomy was done. On further questioning of the patient it was learned that at the age of nine he had fallen from a horse, striking his right side. The probability is that the hernia dates back to this accident. He has gained weight since his operation and his gastric symptoms have disappeared. The interesting observation in this case is that the roentgenologist's attention was so focused on the stomach and duodenal examination that he did not observe the very obvious finding of a loop of intestine in the thoracic cavity.

Case 5.—A man sixty-three years of age was first seen at home on November 10, 1935, by Dr. J. N. Gehlan of Saint Paul, Minnesota. The patient had been in an automobile accident on October 12, 1935. He stated that he fractured three ribs on the left side, that he had an injury to his left hip and back.

Immediately after the injury he was hospitalized and an adhesive dressing was applied to his chest. He developed bronchopneumonia and was in the hospital three weeks, after which he was moved to his home in Saint Paul. At the first examination at his home he said he felt fairly well but was bothered by a persistent cough and considerable expectoration. Examination of the chest showed dullness over the left side posteriorly. The breath sounds were suppressed and coarse râles were heard throughout the right chest. The right border of the heart was six centimeters to the right of the sternum. Abdominal examination showed no abnormalities. There was some tenderness in the lumbosacral region. On November 16, 1935, the cough had increased but the lung findings were unchanged. There was a slight temperature elevation and he complained of some abdominal distress. On November 21, 1935, he complained a great deal of abdominal cramps. The cough had improved but the dullness persisted in the left chest with bronchial breathing on the left side posteriorly. He was then sent to the hospital for x-ray study of his chest and his back, which showed a fracture through the first segment of the sacrum on the left side.

Stereoscopic studies of the chest showed impaired airation of the left lung with elevation and flattening of the diaphragm. There were numerous air-filled pockets with intervening areas of fibrosis. There was an area of consolidation in the base of the left lung, but this was somewhat obscured by a dense cloudiness. The right lung was clear. A diagnosis was made of thickened pleura with trabeculating adhesions in the lower left chest with the possibilities of a small amount of fluid and an area of consolidations in the left base. Because of this rather confusing report and the per-

sistence of the symptoms, the clinician did a thoracentesis which proved negative.

A gastro-intestinal radiograph was made which showed that the entire stomach, all the jejunum, part of the ileum, and a loop of the colon had passed into the left thoracic cavity through a rupture in the left hemi-diaphragm.

I was asked to see the patient November 30, 1935. He was still very nervous and weak, and was having considerable gastric distress and constipation, but as there was apparently no intestinal obstruction, I advised close observation and postponement of the operation until his general condition improved. On May 10, 1936, he was admitted to the hospital and the left phrenic nerve was crushed, and on May 16, 1936, the repair of the hernia was undertaken. A very large opening was found in the left hemi-diaphragm. Fortunately, no adhesions had formed between the abdominal viscera and the pleura. The abdominal viscera was replaced in the abdomen and the defect in the diaphragm was repaired.

The patient had a difficult time for a few days. He was placed in an oxygen tent immediately and the pneumothorax was relieved. After the first week, however, his condition improved and he made a saisfactory recovery. He developed an infection in the lower end of the operative wound and he now has a small incisional hernia. His general health at this time is exceptionally good and roentgenograms taken in July, 1936, and October, 1937, show no evidence of recurrence of the hernia.

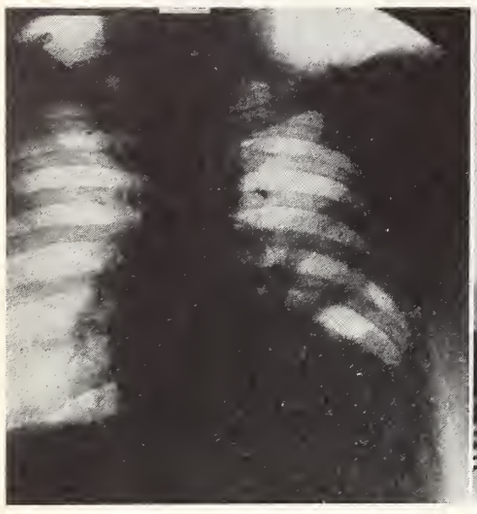

Fig. 9. Case 5. Chest plate showing numerous air-filled pockets with intervening fibrosis.

Fig. 10. Case 5. Entire stomach, the jejunum and part of the ileum seen in left thoracic cavity.

Fig. 11. Case 5. Barium filled colon seen in the left thoracic cavity.

Fig. 12. Case 5. Radiograph taken three months after repair shows no recurrence.

Fig. 13. Case 5. Radiograph taken one and a half years after repair shows no recurrence.

Through the courtesy of Dr. Kano Ikeda, I am able to show a case of congenital diaphragmatic hernia:

Case 6.—One sees from the illustration that the defect is on the left side and the left thoracic cavity is crowded with abdominal viscera pushing the heart and lungs to the right thoracic wall. The radiograph shows the gas filled intestinal loops filling the entire left thoracic cavity. It is readily understood that a hernia of this type is incompatible with life.

The abdominal approach was used in the surgical repair of the cases reported. Ethylene and

ether inhalation anesthesia was employed, and in the case of the large traumatic hernia the administration was by the intratracheal method. The defects in the diaphragm were sutured with silk sutures together with living sutures of fascia lata which were taken from the patient's thigh.

Fig. 14. Case 6. Congenital diaphragmatic hernia with the left thoracic cavity crowded with abdominal viscera.

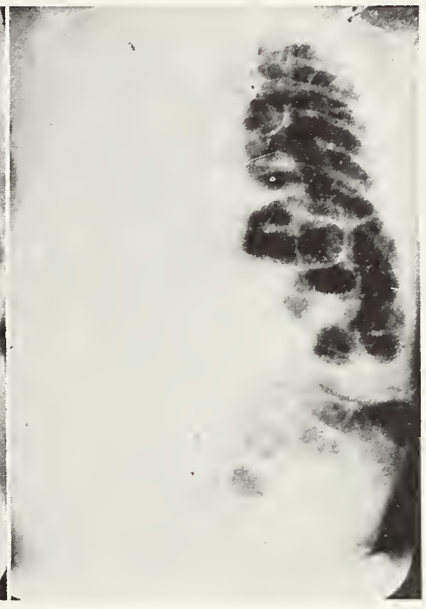

Fig. 15. The gas-filled intestinal loops fitting the entire left thoracic cavity.

In the first case of esophageal hiatus hernia, the hernial sac was removed, but in the second and third cases the stomach was freed from the hernia sac and the sac was allowed to retract into the posterior mediastinum.

It is very important to prepare these patients adequately for operation, as it is a severe operation that is frequently followed by considerable shock. It is therefore advisable to be prepared to use the oxygen tent for several days and blood transfusion will often be of great aid. The cases in which the viscera have been removed from the thoracic cavity frequently develop pleural effusion. This may be very slight but at times it is so extensive that it causes respiratory embarrassment and must be removed.

Summary

1. Improved roentgenologic methods have been a great aid in making a positive diagnosis of a diaphragmatic hernia.

2. A diaphragmatic hernia should always be considered when a confusing problem presents itself concerning the upper abdomen or chest.

3. In all severe chest injuries a careful x ray examination of the chest and gastro-intestinal tract including a barium enema should be carried out to determine the condition of the diaphragm.

4. A thoracentesis is contraindicated until the possibility of a diaphragmatic hernia has been eliminated.

5. Operative repair of the diaphragmatic defect after reduction of the hernia offers the only means of permanent relief.

6. Five cases of diaphragmatic hernia in which operation was performed are here reported. In this group three patients were cured, there is one recurrence and one death.

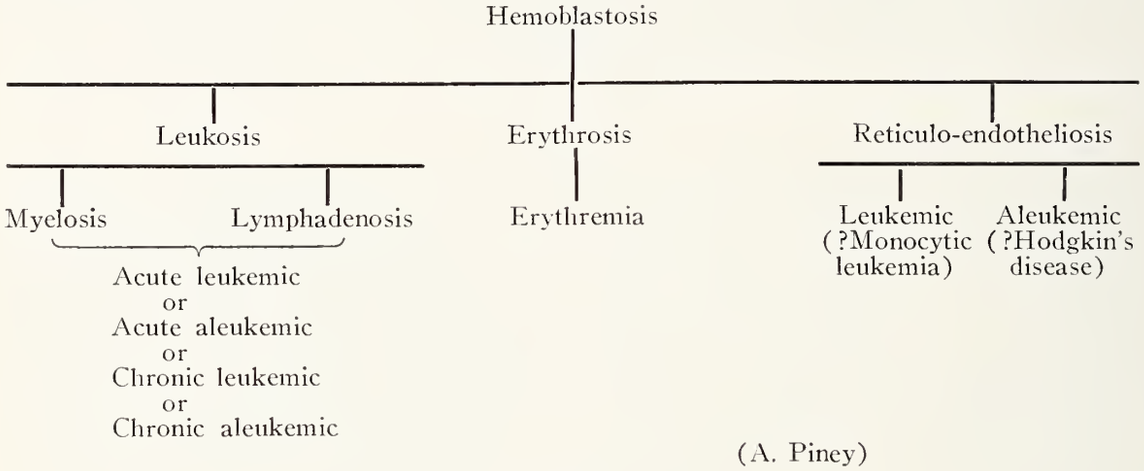
SYMPTOMATOLOGY OF THE VARIOUS LEUKEMIC STATES*

THOMAS A. PEPPARD, M.D.
Minneapolis, Minnesota

I DESIRE to present some observations concerning the symptoms and physical findings in leukemia, based upon a small group of thirty-four cases, and to present a brief clinical record of a few cases of special interest.



Ordinarily the diagnosis of leukemia may be made easily and with assurance. The clinical investigation at once indicates the necessity for an examination of the blood, and if, after this examination, for any reason we are still uncertain, the assistance of an expert blood cytologist in the great majority of instances will promptly and accurately establish the diagnosis. Not infrequently, however, atypical forms of the disease are encountered, and even though we include leukemia in our list of possibilities, we may find that we are unable to do more than this. A given case may at one time present evidence indicating one particular entity, and later give what appears just as good evidence for another. Again, a patient may at one time present the symptoms of a slowly progressive, chronic disease, and at another time show acute manifestations. It is necessary to keep in mind the essential dictum that the disease is one of the hemato-poietic tissues, and that the quantitative and qualitative changes found on blood examination are indicators of the changes going on in the blood forming centers.

The essential cause of the disease is, of course, unknown. At present, most observers class it with the tumors, though some argue for an infectious etiology. The preponderance of opinion and evidence seems to be in favor of the former.

Chart 1 represents Piney's ideas concerning hemato-poiesis.

In Chart 2, I have listed the presenting symptoms in a small series of thirty-four cases. I have grouped them merely as chronic, and acute or subacute. The symptoms are varied, quite as may be found in any text. Any of these individual symptoms alone means little, any of them occurring in a wide variety of conditions. Perhaps in presenting the clinical summaries, I may be able to group them in such a way as to make them mean more. At this point I merely want to comment on a few particular items. Weakness and fatigue were prominent complaints, even though the patient appeared quite robust and no anemia existed.

The frequency of the association of sore mouth, ulceration, necrosis, and bleeding, with the leukemic states (usually acute), recommends to the physician, laryngologist, and dentist, that he consider this relationship, even though a seemingly adequate cause may be present (Vincent's organisms). It is somewhat surprising perhaps that glandular enlargement does not appear with greater frequency; however, I ask you to compare it with the adenopathy in Chart 3 which illustrates the physical findings.

(A. Piney)

CHART 1

*Read before the Minnesota Academy of Medicine, November 10, 1937.

Jaundice was complained of in four cases; cough in six; itching in two; visual disturbance in three; tender eyeball and pain on movement of the eyeball in one instance.

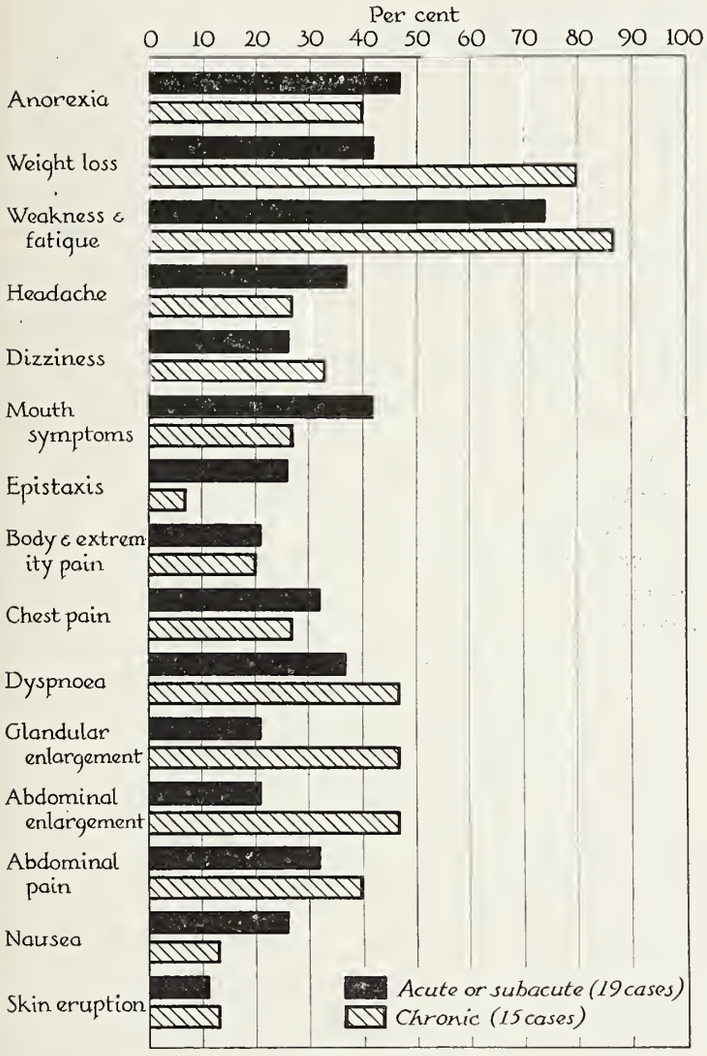


CHART 2. SYMPTOMS

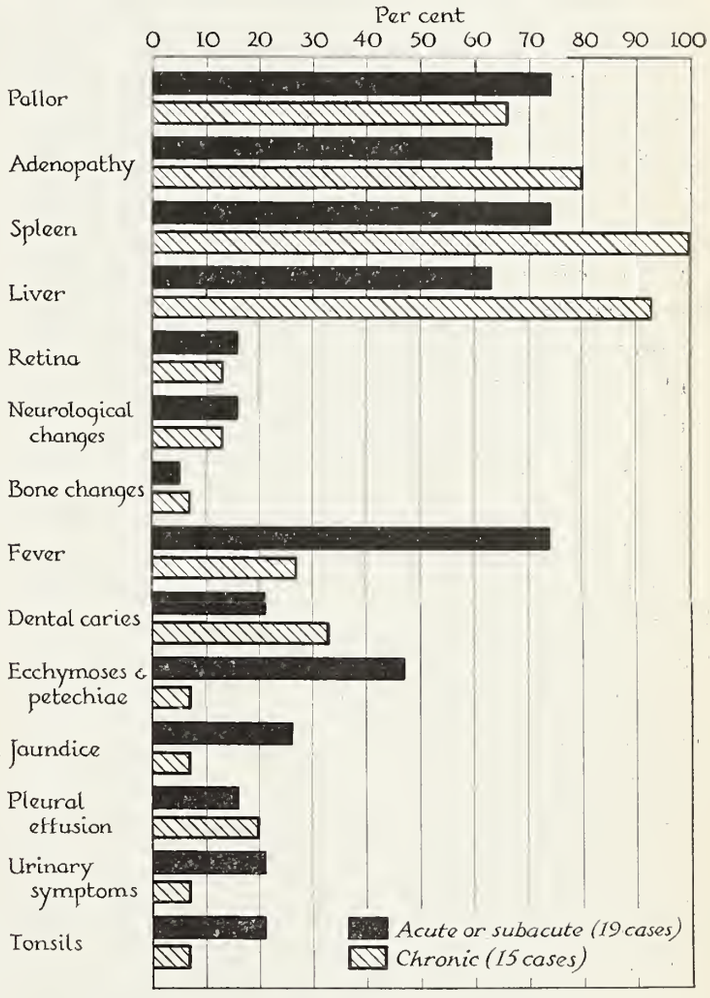

CHART 3. PHYSICAL FINDINGS

It is highly important to pay attention to any skin lesion which may be present, for not infrequently a skin biopsy may be an important factor in determining the true diagnosis.

Priapism, though frequently mentioned, is a symptom which I have never encountered in this disease. Cabot failed to find it in a series of eighty-nine cases.

I have arranged the physical findings in the same general way in Chart 3. There is considerable difference in the degree of glandular enlargement in various parts of the body. The glands are usually discreet, moderately firm, freely moveable, and not attached to the skin or surrounding tissues. Usually the nodes are moderate in size, but not so large as those found in Hodgkin's disease or lympho-sarcoma. Occasionally the mesenteric, retro-peritoneal, and hilus nodes may attain considerable size, though pressure symptoms are not the rule.

In addition to splenic and liver enlargement, these organs may also be tender, the spleen usually more often so than the liver.

The findings in the fundus oculi are principally engorged veins, with or without hemorrhages, with sometimes white streaks along the vessel walls, and increased tortuosity of the vessels. The peculiar color of the fundus is more often talked about than seen. Some authors estimate the incidence of retinal changes in as much as 65 per cent of cases.

Recent articles have commented upon the frequency of neurological findings. These have been carefully looked for, and not found in nearly the frequency reported by Weiss and Schwab (20 per cent).

Bone changes have not been found with any considerable frequency, although tenderness over the bones has been encountered when no lesion could be demonstrated. Sternal tenderness oc-

curred more frequently in the myeloid types. In one patient symptoms were such as to suggest a possible osteomyelitis. One patient had infiltration of the fourth thoracic vertebra which resulted in a pathological fracture and this same person had areas of lessened density in the cranial tables.

The fever naturally more frequent in the acute group was variable and irregular.

Heart murmurs were frequent, sometimes readily explained by sufficient evidence of heart disease, sometimes explainable by the degree of anemia which was present. Subacute bacterial endocarditis may occur terminally as in sepsis. In one case, a child, a leukemic infiltrate had invaded the heart in such a way as to interfere with the coronary circulation and produce abnormal changes in the electrocardiographic tracing.

Case 1 illustrates the course of a patient with lymphoid leukemia whose course was rather longer than usual, with rather acute manifestations near the termination.

Case 2 illustrates rather typically a patient with reticuloendotheliosis.

Case 3 illustrates a hypocytic leukemia with acute symptoms.

Case 4 illustrates a myeloid leukemia which ran a short course.

It would appear that the greatest diagnostic difficulties consist in differentiation from pernicious anemia, Hodgkin's disease, cancer, benign lymph-adenosis, agranulocytosis, and aplastic anemia.

Conclusion.—A characteristic clinical picture together with typical blood findings readily establishes the diagnosis of leukemia. It is, of course, apparent that the qualitative blood changes are of more importance than the quantitative.

Even on encountering a low rather than a high total leukocyte count, leukemia must be considered, and when there is present adenopathy, enlargement of the spleen and liver, bleeding from the mouth or nose, a progressive downhill course, and a rapidly developing anemia, the chances are that leukemia is almost surely present.

Case Reports

Case 1.—A female, fifty-three years of age. Her father had died at the age of sixty-five of cancer of the stomach.

The patient had had no important illnesses. In 1914, she had a "nervous break-down," was in bed for eight months. Since 1923, she had gastrointestinal symptoms, consisting of pain and tenderness in the right upper quadrant, bloating, gaseous eructations, some nausea, and occasional vomiting. There was a tendency to constipation. There had been no jaundice. Menopause had occurred in 1925. She complained of weakness and fatigue, headache, some dizziness, slight dyspnea and palpitation on exertion. Patient had suffered from frequent upper respiratory tract infections.

Physical examination: The patient was well nourished, her color good. Some very small cervical nodes were palpable. Number of non-vital teeth were present. Heart and lungs were normal. The liver was not enlarged, the spleen not palpable. Fundus examination was negative. X-ray examination gave evidence of an abnormally functioning gallbladder.

The patient was seen and examined in 1927 by Dr. L. A. Nippert, who furnished the following findings: Hemoblogin, 77 per cent; erythrocytes, 4,540,000; leukocytes, 40,000, 17 per cent of which were polymorphoneuclears and 83 per cent lymphocytes, "all cells appearing mature and not those usually observed in leukemia."

I observed the patient during the years of 1929 and 1930, during which time her hemoglobin varied from 88 per cent to 83 per cent, the red blood cells from 3,870,000 to 4,480,000, and the total leukocytes from 22,000 to as high as 51,000. Most of the cells were lymphoid in character, but after much study the conclusion was reached that the condition was that of lymphatic leukemia. The Wassermann reaction was negative. The urine was always normal. The stomach contents showed normal findings, and the electrocardiographic tracing was normal. The basal metabolic rate was minus 21 per cent. During this time she was observed over a period of one month by Drs. Giffin and Roundtree, who satisfied themselves that the condition was leukemia, a skin biopsy showing changes characteristic of that condition. While the patient was not incapacitated, her weight diminished from 175 pounds to 157 pounds.

The patient was not observed from 1931-1933, but it was learned that she was receiving x-ray treatments. In August, 1933, she had some dental extractions and there was no excess bleeding.

In 1934, and up to March, 1935, she was observed by Dr. J. Davis of Minneapolis, who reported the findings as follows: Patient had lost in weight to 125 pounds by March, 1934. There was general lymph adenopathy, and the spleen was enlarged and palpable. Hemoglobin was 68 per cent, red blood cells 3,000,000, leukocytes 47,000. From the blood smears, the diagnosis was obvious, there being many immature forms. From this time the condition was progressive, the hemoglobin going down to 20 per cent, red blood cells 1,000,000, leukocytes 57,000 on February 28, 1935. There was considerable bleeding from the nose and mouth. Transfusions and the administration of liver did not modify the course, and the patient died March 1, 1935.

Diagnosis: Chronic lymphatic leukemia.

Comment.—Information is available concerning this patient over a period of approximately eight years. It is not uncommon to observe some of these patients with more or less characteristic blood changes, but with all relatively little impairment of the state of their general health. In the present instance the condition lasted longer than the average duration of about four years. Near the termination the symptoms become more acute.

Case 2.—R. L., a female, forty-nine years of age. Family history was unimportant.

The patient's general health had been good. Appendectomy had been performed in 1910. Radium had been applied to the pelvis in 1932, and she was said to have been anemic since 1932.

Following dental extraction, May 21, 1935, she bled profusely, was faint and weak, the face and jaw swelled, and there was a bad odor to the breath and a bad taste in the mouth. A chill occurred May 27, 1935, and the following day she entered the hospital.

Examination: The patient appeared well nourished; weight, 132 pounds. There was a marked pallor, swelling of the left lower jaw, but no fluctuation. Blood oozed from the gum margins, and there were large necrotic areas in the mouth. The regional lymph nodes were enlarged. Heart and lungs were normal. The abdomen was distended and the liver and spleen were not palpable. There was no general adenopathy.

Laboratory: hemoglobin at the time of admission was 37 per cent, red blood cells 1,500,000, leukocytes 1,000. Subsequently, the hemoglobin varied between 40 and 46 per cent. Three transfusions were given, and the red count was elevated to as high as 2,700,000. The leukocyte count varied from as low as 300 cells to as high as 2,400, the polymorphonuclear percentage generally about 20. There was variation in size and shape of the red cells and a few early forms were seen. There was some evidence of regeneration. The platelet count was 190,000 and on another occasion 250,000. The blood culture was negative. Smears from the mouth showed Vincent's organisms.

Course: Fever ranged from 101 to 104.6 degrees, the pulse rate increasing in proportion to the temperature. There was much nausea, headache and weakness, and constant oozing from the mouth and gums. X-ray of the jaw showed infected area in the region of the tooth socket. There were ecchymoses and on June 5th frank hematuria. On June 9, hemiplegia, extensive retinal hemorrhage and coma supervened. Death occurred on this day.

Autopsy: Peritoneum, pleura, and pericardium were negative. The heart weighed 250 grams, and was entirely normal. The lungs were normal. The spleen weighed 250 gms., its cut surface appeared normal, and there was hyperplasia of the reticulum. The right kidney weighed 200 gms., the left was 175 gms., and they were normal except for blood in the pelvis. There was no general adenopathy. The rib marrow was not gelatinous; the marrow of the middle of the femur was yellow but section shows hyperplasia, with mainly large round cells which showed no differentiation toward mature granulocytes or erythrocytes. There was no infiltration of the liver, lung, or kidneys.

Blood smears were reviewed by Dr. Downey who found the red blood cells and lymphocytes normal. A number of cells were found with rounded or indented nuclei with chromatin network resembling myeloblasts, the same as those found in the splenic sinuses and bone marrow which were termed differentiated reticulo-endothelial cells.

Diagnosis: Reticulo-endotheliosis (Monocytic leukemia).

Comment.—The extensive necrosis in the mouth is quite characteristic of this type of leukemia, the course of which is acute. The profound anemia serves to differentiate this condition from agranulocytosis. The head was not opened at autopsy, but quite likely there was a terminal cerebral hemorrhage.

Case 3—A. B., a male, thirty-one years of age. Family history unimportant.

History: This man had had childhood diseases without complications, influenza in 1918, gonorrhea in 1921, and fibrinous pleurisy in 1929. Syphilis was denied.

In October, 1935, he had an attack of abdominal pain, probably unaccompanied by fever, and constipation, and a surgeon considered the possibility of intestinal obstruction. After ten days he returned to work, was not up to par, but had no specific complaints.

On April 2, 1936, he experienced a moderately severe epigastric pain, dysphagia, a sense of pressure in the upper abdomen with tenderness, and loose bowel movements. There was a ten pound weight loss in two weeks. He complained of weakness, nocturia (1-3), dark urine, throat irritation, cough, and whitish sputum.

On April 12, 1936, he entered the hospital.

Examination: Well nourished, weight 172 pounds, slight pallor, conjunctivæ icteric, ecchymoses, no general adenopathy. Lungs showed a shading at the left base, impaired resonance, over the lower third of the right base, diaphragmatic excursion, no pleural rubs. Heart normal, blood pressure 118/80. Liver extended 6.5 cm. below the tip of the ensiform, 5 cm. below the costal margin in the mid-clavicular line. Spleen extended half way from the costal margin to the umbilicus. A slight amount of peritoneal fluid was present. Rectal examination was negative.

Laboratory: Urine—the only significant finding was that of 4 plus urobilin and urobilinogen. The icterus index was 23. There was no increased fragility of the red cells. Bleeding time and clotting time were normal. One blood culture remained sterile. Blood Wassermann was negative. The hemoglobin, on admission, was 82 per cent, after two weeks 51 per cent, and thereafter varied between 55-48 per cent. Red blood count was 4,400,000, later reduced to 3,420,000. Leukocyte count varied from 2,900 to 3,400; differential: polymor-

phonuclears 77 per cent, lymphocytes 15 per cent, monocytes 8 per cent. One normoblast was observed, and no early leukocyte forms were seen at any time. Sputum was negative for tubercle bacilli. Twenty-five mgm. of urobilinogen was excreted in the urine in twenty-four hours; 350 mgm. urobilinogen in the stool. Cystoscopic examination and pyelograms were negative.

Autopsy: The heart weighed 250 gms. and there was a slight thickening of the edges of the mitral cusps, but no ulcerations nor fresh vegetations. The other valves were normal. The coronary vessels were normal. A minimal atheroma of the aorta was present.

The lungs were normal. At the hilum of the right lung was a mass of glands, 12 x 8 x 6 cm.

The spleen weighed 1,350 gms. The external and cut surfaces were studded with a large number of whitish firm nodules up to 5 cm. in diameter.

The liver weighed 4,050 gms., and was congested. There were numerous white nodules throughout, similar to those found in the spleen.

The right kidneys weighed 250 gms., the left 300 gms. They were pale and firm, and a 4 mm. nodule was present in the cortex of the right kidney.

Microscopic examination of nodules in the liver and spleen showed masses of cells resembling lymphocytes; much mitoses. The mediastinal lymph nodes showed leukemic metaplasia and also some necrosis. The kidney contained no leukemic infiltration in the parenchyma, but a subcapsular leukemic nodule. Imprint preparations from spleen and liver nodules showed large numbers of immature lymphocytes. Bone marrow of ribs and sternum appeared hyperplastic. On review of blood smears, no abnormal cells were found.

Course: There was irregular fever, with diurnal variations of from one to three degrees, gradually increasing from 100 degrees F. to 102. Pulse rate followed the temperature curve, increasing from a level of about 100 to 120. There was increasing weakness. There were attacks of abdominal pain with increasing distention of the abdomen. The liver and spleen enlarged. Ascites and dependent edema developed. There was sore mouth and nose bleed on occasion. The patient coughed and expectorated a clear mucoid material. The jaundice varied in intensity. He was given a transfusion of citrated blood on April 28, and on May 5, but became weaker and died on May 8.

Diagnosis: Aleukemic lymphoid leukemia.

Comment.—This patient died approximately thirty-six days after the development of his acute symptoms. The symptoms of cough and expectoration as well as difficulty in swallowing were undoubtedly related to the mediastinal glandular enlargement. Jaundice is not infrequently observed in the leukemias. It should scarcely be necessary to call attention to the fact that the term aleukemic refers to the absence of characteristic early leukocytic forms of cells in the circulating blood, and does not at all pertain to the total number of leukocytes. The not infrequent misapplication of the term has been one of the reasons for various attempts at altering the nomenclature, bringing forward such terms as hypocytic, hypercytic and normocytic to designate low, high, and normal total leukocyte counts. No especial need is seen for changing the terminology. Proper use of the present terms, with the necessary qualifications, very well suffices.

Case 4. (Courtesy of Dr. R. L. Sherer).—Male, sixty-two years of age. Family history was unimportant. Previous health had been good.

Acute onset occurred May 14, 1936, with nausea, vomiting, weakness and diarrhea. There were some body pains and chest pains, with increasing weakness and loss of weight.

Examination: A pallor, with slight icteric tinge was present. Fundus oculi were negative. There was moderate atherosclerosis. Blood pressure 140/90. Heart and lungs were normal. The spleen and liver were palpable and both moderately enlarged. Tendon reflexes were normal. Vibration sense was diminished over the lower extremities. The electrocardiographic tracing showed myocardial degeneration.

The patient entered the hospital June 2, 1936.

Laboratory findings: Hemoglobin was 45 per cent, red blood cells 1,980,000, white blood cells 5,800, 52 per cent of which were lymphocytes. There was considerable albuminuria with cylindruria. Test meal showed achlorhydria before and after histamine. Blood urea nitrogen on one occasion was 10 mgm., later as high as 29 mgm. Blood culture was negative. Subsequently, the hemoglobin varied between 40-35 per cent. There was little change in the number of red cells. After one week's time the total leukocyte count increased to 13,000; on June 16, it was 16,000, and on June 20, 20,000. There was gradual progressive increase in the immature forms of white cells, and although the anemia, the appearance of icterus, the achlorhydria, and the diminished vibration sense first suggested pernicious anemia, later study of the blood smears made the diagnosis apparent.

There was temperature variation from 98 to as high as 101 degrees. The patient expired June 24, 1936.

Partial autopsy only could be obtained. The spleen weighed 750 grams. The kidneys weighed 200 and 235 gms. The liver appeared to be of about normal size and weight. Sections of these organs showed leukemic infiltration. Diagnosis: Acute myeloid leukemia.

Comment.—In the present instance, as in not a few others, pernicious anemia was first suggested, not only by the general appearance of the patient, but by certain of the laboratory findings. While during the first week, treatment with liver extract produced a reticulocyte increase to 9 per cent, there was no improvement in the red blood cells, nor the hemoglobin.

A CASE OF WOHLFAHRTIA VIGIL CUTANEOUS MYIASIS IN MINNESOTA

CHARLES VANDERSLUIS, M.D., and D. D. WHITTEMORE, M.D.
Bemidji, Minnesota

"CUTANEOUS myiasis," as was so aptly stated by Walker,[10] "is an infestation of the skin and subcutaneous tissues by the larvæ of certain species of flies which feed upon these tissues during their period of growth, causing great suffering and often leading to secondary bacterial infection." With the invaluable assistance of Drs. William A. Riley and Reed O. Christenson of the Department of Entomology, University of Minnesota, we are able to present a proven case of cutaneous infestation of a young infant in Minnesota by maggots of the flesh fly *Wohlfahrtia vigil.*

M. B., a female infant of two and a half months, living in Crookston, Minnesota, presented a few small red pimples on her upper chest the morning of July 10, 1937. The mother observed that they became larger during the day, but she considered them due to the heat. Towards night the infant became irritable and began to cry. She cried all night in evident pain. She was brought to Bemidji on a visit the next morning, continuing to cry violently. The pimples on her chest became larger, were capped by yellowish white heads, and were surrounded by areas of redness and induration. The inflammatory bases of many closely grouped lesions on the right upper chest fused. That noon the mother suddenly noted lively crawling worms emerging from the pimples on the infant's chest, and she rushed the baby to us in great excitement. We noted about fifteen red macules, ten of them closely grouped on the upper right chest, and the rest scattered singly in the left axilla, left scapular region and left loin. The single lesions were like large, well developed acne pustules. The maggots were emerging from the confluent lesions on the upper chest, occupying an area about 6 x 8 cm. These lesions were the most advanced and seven or eight of them presented, at the apices, cleanly punched-out holes measuring about 3 mm. across. Each was surrounded by a small red area, and the deeper surrounding tissue was indurated. These holes contained the maggots. In most of the openings only one maggot was present but in several of them two and three were wriggling deep in the infant's hypoderm. In some areas the skin was undermined by tunnels between the holes, leaving but a fibrotic bloodless skeletal subcutaneous network. The maggots were actively feeding on the infant's tissues and when expressed or picked from an opening would rapidly crawl across the skin and enter another if possible. In some of the lesions not quite ruptured, maggots could be seen moving about under the inflamed necrotic epidermis. At least one maggot could be expressed from each lesion, and such was the procedure followed in treatment.

On the anterior chest wall several free incisions were made to open up the tunneled hypoderm. The maggots

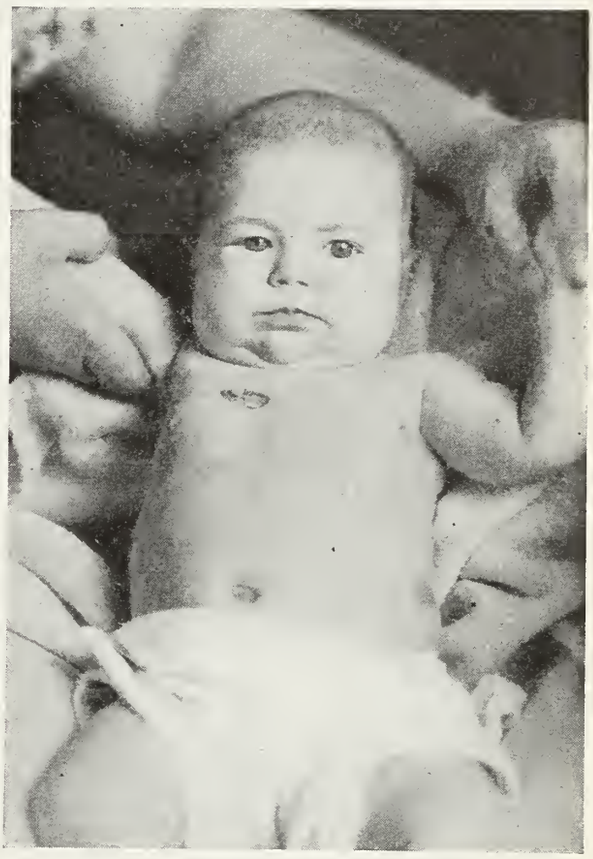

Fig. 1. Infant in authors' case.

were white, round, and segmented, measuring 4 to 8 mm. in length, and each had a black speck at the head. All of them, numbering about twenty, were removed from the baby and several placed in alcohol-formalin solution for study. It was noted that they lived several minutes in this preservative. The infant went to sleep immediately after all the larvæ had been removed. We placed azochloramid packs on the lesions and were forced to lose contact with the baby, due to the parents' anxiety to return to Crookston. Dr. W. F. Mercil saw the patient there and reported finding no more maggots. The child recovered uneventfully with treatment directed to clearing up the secondary inflammation from pus organisms (undoubtedly staphylococcus). The photograph represents the infant about one week following removal of the larvæ. Dr. Reed Christenson identified them as second stage larvæ of the Sarcophagid fly, *Wohlfahrtia vigil.*

Cutaneous myiasis is a medical curiosity in temperate parts of the United States, although it is not infrequent in the southern states. For

many years it has been considered that the most common cause of human myiasis in the Western World is a Sarcophagid fly, *Cochliomyia macellaria,* which has been reported from Canada to the Argentine. It has been thought to have a "screw-worm" larva. It is somewhat larger than the housefly and deposits numerous eggs in open wounds, or in the nose or ear of individuals with a purulent discharge or odor which attracts the adult flies. Harris,[6] who reported a number of cases of screw-worm infestation, says that the larvæ may issue within a short time and begin at once to feed and burrow into all structures and cavities of the head, migrating into the eyes, middle ear, and brain, destroying tissues and causing infection and gangrene of soft parts and necrosis of bone. The larvæ then desert the host to pupate in five to fourteen days, leaving behind widespread devastation. Discharge of larvæ, and sero-sanguinous fluid, and the odor of wet gangrene are listed as the cardinal symptoms of infestation. The mortality is variously reported to run from 15 to 85 per cent.

In 1933, Cushing and Patton[2] made the astonishing discovery that the true "screw-worm" is the larva of a related but entirely distinct species, which they proposed to call *Cochliomyia americana.* It is this species which invades living tissue after entering through some wound. For a half century or more, *Cochliomyia macellaria,* a secondary invader, has been held responsible for invasions of living tissue which were really due to *C. americana.* The resultant confusion in medical and veterinary literature is such that case reports of the past must all be regarded with suspicion.[8]

Another family of flies, the Œstridæ, includes species whose larvæ are parasitic in animals and, occasionally, in man. Of these the bot-fly larvæ are commonly found in the stomach and intestine of horses. The eggs are laid on the hairs of the host and, when licked up, the larvæ enter the alimentary canal, where they remain until mature, when they are discharged in the manure and enter the ground to pupate. In the rare cases of human infection the larvæ are deposited on the skin, hatch, and penetrate the skin, moving about under the surface superficially and producing a characteristic creeping eruption, larva migrans, with narrow, slightly elevated, red, linear lesions. Its occasional resemblance to scabies has been remarked. *Gastrophilus* is the most frequently cited causative genus.

Very different is the biology of the warble flies of cattle.[4] Here the eggs are likewise laid on hairs but the hatching larvæ bore into the skin of the animal host and migrate for months in the body tissues before they come to lie under the skin of the back in mid-winter. The rare human infections do not present the raised inflamed line of creeping eruption, but the larvæ migrate in the deeper tissues, occasionally manifesting their presence by tumor-like swellings and severe pain along the path of migration. Such a traveling lump may surpass the size of a pigeon egg, have the appearance of a furuncle, and, at the end of its migration, the warble stage, present a central opening on its surface in which the larva can be seen "appearing and disappearing after the manner of a jack-in-the-box."[1] This disease has been variously named as dermal myiasis, subcutaneous myiasis, and ox-warble disease. The larvæ of *Hypoderma lineata* and *H. bovis* have been identified as invaders in lesions of the above type. The so-called human bot *Dermatobia hominis* enters the unbroken skin (Dunn[3]) and produces similar painful tumors (non-migrating).

Wohfahrtia vigil as a human and animal parasite is little known about and has been found only in Canada and the northern part of the United States, due largely to the work of E. M. Walker[11] of the University of Toronto. Brauer and von Berganstamm in 1889 erected the genus Wohlfahrtia for certain flesh flies of the family Muscidæ formerly included in the genus Sarcophila. W. magnifica, the type species, is well known as a parasite of man and various domestic animals in Europe, particularly Russia, and has been considered the European analogue of our screw-worm fly. In all these cases the larvæ are noted to feed upon the mucous membrane and deeper tissues of the nose, gums, ear, and even the eye, but Walker finds no mention made of the larvæ ever penetrating the healthy skin, as must have occurred in the cases of infestation by W. vigil.

Nothing had been known of the larval habits of the North American species of Wohlfahrtia until the discovery of W. vigil as the cause of human cutaneous myiasis in Toronto in 1919 by Walker.[11] In 1931 he reported a total of sixteen cases having come to light since 1919, all

in Canada and the northern United States. In 1934 there were four additional cases in Toronto besides 180 proven cases of Wohlfahrtia myiasis in dogs, cats, foxes, milk, ferrets, and rabbits.

Dr. A. A. Kingscote of the Ontario Veterinary College, who reported the animal cases, says that "in very small animals from five to twenty larvæ will cause death usually within about ten days." There are isolated human cases reported in New York (Felt, 1925), New Hampshire (Sanders, 1928),[9] Colorado (Knowles, 1925),[7] and lately North Dakota (Gertson, 1933),[5] the latter place only a few miles from Crookston. Dr. J. M. Aldrich, of the National Museum, writes: "The species ranges from Nova Scotia to North Dakota, or rarely further, but west of the Rocky Mountains it seems to be replaced by . . . Wohlfahrtia meigenii Shiner," a form which is not parasitic in the manner W. vigil is. Our case in Crookston appears to be the first reported in Minnesota, although a suspicious case was observed in the region of Duluth recently. Dr. Riley reports the death of many young mink, young foxes, and some cases of very young rabbits from the attacks of larvæ in this region, and he urged upon us the report of this human case.

All but one of the human cases of myiasis have occurred in infants less than one year of age, the average being two to five months. Felt reported the adult case of a conjunctival cyst filled with "living maggots provisionally identified as W. vigil." The small abscess-like lesions develop most commonly on the neck, chest, shoulders, and arms, showing our case typical in this respect. Lesions have also been observed on the palm, navel, cheek, and eyelids. In Walker's original words: "The small opening at the apex of the lesion is so strongly suggestive . . . of pus that on superficial examination a group of lesions might readily be considered impetigo; in fact, the diagnosis of impetigo was made erroneously in at least one of the cases reported. On closer examination it is readily seen that what appeared to be pus is, in reality, the posterior end of the larva. This may be seen to be moving . . . if pressure is exerted the larval body may be forced out. It can be seen to work its way by a wriggling movement along the skin surface. In most cases about twelve or fourteen of these lesions were present, each with an external opening, and each containing one or more larvæ. In the earlier stages a slight macular rash may be present and at this time the young larvæ, 2 to 3 mm. long, may be found wandering over the surface of the skin. It thus appears that the larvæ may penetrate the skin at points distant from those where they were deposited by the parent fly. The development of the larvæ is very rapid, though variable. Scarcely more than 2 mm. long when born, they reach a length of about 20 mm. in from four to twelve days. In another day or two they emerge from the skin and drop to the ground and burrow into the earth and become puparia. After about eighteen days in this resting stage they emerge from the ground as adult flies. Most of the cases of myiasis due to this fly have occurred in June. The adult flies have been taken at various times during the summer months and have been found from the New England States to Alaska.

Norma Ford,[4] through her studies of W. vigil in the field and in the laboratory, has learned much about the habits of the species. It is closely related to the house-fly and the blow-fly or "blue bottle," but unlike these diptera it does not breed in decomposing organic matter but rather is parasitic on living tissues. Experimentally it can be observed to prefer the eye of a living guinea pig to liver. Unlike the majority of common flies it deposits living larvæ or maggots instead of eggs, although rarely it has been observed to lay eggs when unduly excited or attracted to a favorable spot on a living animal. In feeding experiments it has been noted to pass up meat in favor of milk, sugar, and flowers. The flies are not attracted by the odors of decomposing substances. Ford found that all of the infested infants had been sleeping unprotected out-of-doors and that many had been living near a railroad track. She found that the flies were attracted by warmth and so stimulated to larviposition; thus she explains their greater activity near a warm railroad track in the summer. She also noted the greater activity of the females in the absence of direct sunlight, an interesting observation in view of the fact that a child is usually placed in a cool shady place when left outside. She remarked that in no case had the fly been known to enter houses. In our case an exception may have occurred, since the

mother states that at no time in the week preceding infection had the infant been left out-of-doors. The maggots were estimated to be about three days old. The nearest railroad track was three-fourths mile away.

If additional cases are encountered it is suggested that some of the living maggots be placed on raw meat and also some preserved in 70 per cent alcohol and sent to an entomologist. Again we wish to express our gratitude to Dr. W. A. Riley for his interest and many helpful notations.

RELATIVE VALUE OF THE DIAGNOSTIC PROCEDURES IN THE ALLERGIC CHILD*

ALBERT V. STOESSER, M.D., and ROLLIN E. CUTTS, M.D.

Minneapolis, Minnesota

CUTANEOUS tests and trial or elimination diets play an important part in the diagnosis and treatment of allergic disorders of the child. Much has been written concerning the value of dermal testing in determining the causative agent in allergic disease. Early reports in the literature were chiefly concerned with the scratch method. The introduction of the intracutaneous method marked the onset of a controversy as to the relative merits of the two main methods of cutaneous testing. The pioneer investigators used extracts and solutions which had been crudely prepared and they differed greatly in their testing technic. It is not surprising, therefore, that these workers could come to no significant agreement on the matter.

Today the powdered and fluid extracts are definitely more potent than they were a decade ago and their quality will continue to improve. The powdered extracts need no longer be used for the scratch method. Glycerinized concentrated liquid extracts are now available. This material has led to the introduction of another technic. In place of the customary scratch through the upper layer of the epidermis, oblique and shallow punctures are made. This procedure is referred to as the pressure-puncture method of cutaneous testing. It is a relatively painless procedure when properly performed and small children will tolerate it with little complaint.

The pressure-puncture method was adopted by the staff of the Pediatric Allergy Clinic of the University Hospital, the following technic being employed. The skin is cleansed with alcohol or ether or both and allowed to dry. The various glycerinized fluid extracts are then expelled from the glass capillary tubes upon the cleansed skin at intervals of about four centimeters. With a sterile sewing needle held nearly parallel with the skin, four to eight oblique pricks or shallow punctures are made into the epidermis by pressing the point of the needle through each drop of extract. A new needle is used for each test. The punctures are confined to an area not more than three millimeters in diameter.

Sufficient fluid extract to produce a positive reaction in susceptible children is carried into the epidermis by the multiple punctures and in a few minutes the excess fluid on the surface of the skin is gently wiped off. A similar test is carried out with a control glycerine solution and only those reactions in the test sites which are distinctly greater in intensity than that resulting from the control test are considered positive. The positive reactions (urticarial wheal surroundered by a zone of erythema) usually appear in sensitive patients in twenty to thirty minutes.

Three hundred consecutive cases of allergy in

*From the Allergy Clinic and Service of the Department of Pediatrics, University of Minnesota. Presented before the Fall meeting of the Southwestern Minnesota Medical Society at Fulda, Minnesota, October 7, 1937.

TABLE I. CLINICAL VALUE OF THE PRESSURE-PUNCTURE CUTANEOUS TESTS IN 300 ALLERGIC CHILDREN

Allergic Disease	No. of Cases	Results of Treatment Based on Tests			
		Good		Poor	
		No. Cases	Per Cent	No. Cases	Per Cent

Urticaria and Gastro-intestinal Allergy	16	10	63	6	37
Total	147	39	27	108	73

the child were tested by the method just described. The children ranged in age from six months to fifteen years. In 144 cases or 48 per cent the tests were of definite value in determining the exciting cause in the various allergic manifestations. The best results were obtained in hay fever and bronchial asthma. The causative agent was easily found in 80 per cent of the children with hay fever and in 62 per cent of those suffering with asthma. Only about 33 per cent of the cases of eczema gave positive skin tests which were found to be of clinical significance. Allergic rhinitis, urticaria and gastro-intestinal allergy made a poor showing. The results are summarized in Table I.

In 156 cases the pressure-puncture tests were of no value, and these children were not subjected at once to the intracutaneous testing. This method is painful and often rather difficult to perform properly on the child. Therefore, the elimination diets were tried. The nine children with hay fever were omitted, leaving 147 cases. It was found that milk, cheese, egg, whole wheat, white potato, chocolate, tomato and orange were most frequently the offending foods. In thirty-nine cases the response to the trial diets was satisfactory. The best results were in urticaria, with eczema, and allergic rhinitis next. Those in bronchial asthma were the poorest, as may be observed in Table II.

The intracutaneous tests were next considered. The food allergens were placed in various groups in order to simplify testing but the inhalants were not mixed together. Pollens were excluded and therefore the nine cases of hay fever unsuccessfully treated were not tested. One hundred and eight children received the intradermal tests, the following technic being employed. The

outer aspect of the arm or the anterior aspect of the thigh is used. The skin is cleansed with alcohol and dried. A graduated 1 c.c. (tuberculin) syringe with a hypodermic needle of 27 gauge and a half inch in length is selected. After loading the syringe and ejecting all air bubbles, the needle is inserted into the corium through the integument. Not more than 0.01 c.c. of the sterile extract is injected. Control tests are similarly made with sterile extracting fluid. The tests are observed and read within ten to fifteen minutes.

In thirty-eight children good results were obtained by treatment based on the intracutaneous method of testing. Excellent results were obtained in the allergic rhinitis cases, the causative agent being found in 86 per cent of the children. Assistance was obtained in determining the underlying cause in 39 per cent of the children suffering with bronchial asthma. In eczema, however, the results were poor and the tests were of no value in the few remaining cases of urticaria. Table III present the results.

Interesting observations were made in the thirty-eight children responding favorable to the treatment based on the results of the intracutaneous technic when the positive reactions were compared with those previously obtained with the pressure-puncture method. The intradermal tests gave sets of positive reactions which often did not correspond very colsely with the positive tests of the pressure-puncture technic. Patients sensitive by skin testing to egg, milk or cereals by one method were found to give positive reactions to meats, vegetables or fruits by the other method. Food sensitivity by the pressure-puncture technic was found to be supplemented or replaced by inhalant sensitivity, by the intracutaneous technic, or the reverse might be true. For the sake of economy and clearness the data are summarized in Table IV. The children with definite positive tests by both methods are listed first and are followed by those in whom the pressure-puncture tests gave weak reactions to many allergens.

Incidentally the remaining seventy children in whom the intracutaneous tests were of no assistance in determining the cause of the allergic condition were subjected to less specific forms of treatment. In the cases of eczema, crude coal tar or its derivatives were used extensively. The orders concerning the application of the tar were properly carried out in twenty-four children and fairly satisfactory relief was obtained, leaving ten children in whom the eczema was not controlled. The children with bronchial asthma were again examined and, in view of the poor response to the cutaneous tests, infection was now considered the most important cause of the asthmatic attacks. Tonsillectomy and adenoidectomy together with puncture and irrigation of the maxillary sinuses in some of the children was recommended. The operation was followed by prompt relief in eleven children, leaving sixteen cases in whom all forms of treatment were unsuccessful. The removal of the tonsils and adenoids gave relief to four of the six remaining children with urticaria and to the three with allergic rhinitis.

Summary and Conclusions

Three hundred cases of allergic disease in the child were subjected to a rather thorough investigation involving the various acceptable diagnostic procedures. This study yielded data of considerable value in determining the proper method of diagnosis and treatment for each allergic disorder.

First, the pressure-puncture cutaneous tests using glycerinized concentrated liquid extracts were applied to all the children. This technic was found to be tolerated by children of all ages from infancy through puberty.

1. The results of the treatment based on the positive reactions were satisfactory in 144, or 48 per cent, of the cases.
2. The procedure was of greatest value in hay fever and bronchial asthma, and of little value in allergic rhinitis, urticaria, and gastro-intestinal allergy.

Second, the elimination diets were tried. Excluding nine cases of hay fever, the diets were given to the remaining 147 children.

1. Thirty-nine of the cases, or 27 per cent, responded favorably.
2. The best results were obtained in urticaria and gastro-intestinal allergy. Only one-third of the cases of eczema and one-fourth of the cases of allergic rhinitis were helped by the diets. Little assistance was secured in bronchial asthma.

Third, the intracutaneous tests were applied to the 108 children who did not respond to the trial diets.

1. Treatment based on the results of this technic was satisfactory in thirty-eight, or 35 per cent of the cases.
2. The procedure was of greatest value in allergic rhinitis, and assistance was obtained in determining the causative agent or allergen in 39 per cent of the cases of asthma. Eczema made a poor showing.

These observations indicate that the allergic child could be treated with a minimum of time and effort if some attention was given to the fact that each allergic disease has a diagnostic procedure or procedures to which it responds best. In eczema the elimination diets and pressure-puncture tests are of greatest value; in allergic rhinitis, the intracutaneous tests; in hay fever, the pressure-puncture tests; in bronchial asthma, the pressure-puncture and intracutaneous tests; and in urticaria and gastro-intestinal allergy, the elimination diets.

CASE REPORT

ACUTE DISSEMINATED LUPUS ERYTHEMATOSUS ASSOCIATED WITH MILIARY TUBERCULOSIS*

R. G. HINCKLEY, M.D., and C. A. McKINLAY, M.D.

Minneapolis, Minnesota

A PARTIAL review of the literature indicates that the association of acute disseminated lupus erythematosus with miliary tuberculosis has been of such relative rarity as to make this case of interest in that respect.

The patient, a male Hawaiian of Japanese extraction, twenty-five years of age, was admitted to the Students' Health Service on May 17, 1937. Prior to this illness, on admission to the University on September 27, 1932, the patient had been given a thorough routine physical examination. The findings at that time had been essentially negative, except for a positive Mantoux test (1-10,000 dilution), which was followed by a routine x-ray film of the chest, reported as negative on January 23, 1933.

History.—The illness began five days before admission, with chills, fever, and a dull ache between the shoulders, which became progressively worse. The patient stated that he had felt fairly comfortable when warm and in bed. Pain and chills had been simultaneous and frequent, but without regularity. Other complaints included occasional paroxysms of nonproducive coughing and sensation of "heaviness in the chest."

Signs, Symptoms, and Clinical Course.—Examination on admission revealed a moderately inflamed pharynx, positive findings on the right side of the chest, temperature 104 degrees, pulse 118, and respiration 22. The positive chest findings were decreased motion on the right, dullness to percussion over the right base anteriorly and laterally, and massive showers of coarse, moist rales throughout the right lung above the area of dullness.

These signs and initial symptoms rapidly subsided. By the sixth day, the patient was apparently normal except for persistent constipation and minimal chest findings of a small area of decreased breath sounds and reinforced vocal resonance anteriorly at the right base and a few scattered sibilant rales posteriorly. The temperature began again to rise and leveled off at an approximate daily variation of 100 to 102 degrees; the constipation persisted; and a punctate erythematous rash appeared over the abdomen (May 27). Again the temperature mounted to an approximate level of daily variation from 102 to 105 degrees for one week (a peak of 105.6 degrees on June 1). The constipation was followed by diarrhea, and the abdominal rash altered to a generalized erythematous maculopapular eruption—most marked on the trunk, but including the buccal mucosa. This rapidly became deeper in hue, morbiliform in character, and frankly coalescent. There was a moderate photophobia but no coryzal symptoms.

This rash faded in color, altered in character, and gradually localized primarily to the neck, face, knees, and elbows (June 3), but remained evident for the extent of the case. Cervical adenitis and mild bilateral palpebral conjunctivitis (similar to the general skin reaction) were noted. The face became edematous with brawny appearing skin, some grayish scaling and a V-line distribution over the neck and butterfly distribution over the nose and cheeks gradually becoming apparent. The temperature moderated but continued fairly constant throughout at an approximate daily variation of maximum peaks of 101 to 103 degrees. About the middle of this course (June 10) there was a very brief period of air hunger and rusty sputum which was probably an untoward therapeutic result. Gastro-intestinal upsets, with nausea and vomiting and an occasional period of diarrhea, were frequent in the latter period of illness. The patient was rational, and coöperative, except for brief periods of occasional delirium late in the afternoons of the last month. Bilateral chest signs were noted during the last month. The patient grew progressively moribund, and showed a profound terminal cachexia.

On August 3, the patient drank one and a half ounces of merthiolate solution—apparently with suicidal intent. When seen by the physician, he was nervous, sweating profusely, responsive and fully aware of the circumstances. The blood pressure was 70/0 and the pulse regular, extremely rapid, weak and

*From the Department of Preventive Medicine and the Students' Health Service of the University of Minnesota. Presented before the Minnesota Society of Internal Medicine, Nov. 8, 1937.

thready. Following emergency treatment and restorative attempts, signs of acute pulmonary edema developed, and on August 4 the patient expired.

Laboratory Studies.—Chest x-rays taken on May 18, May 25, June 1 and June 3 were all reported negative. One on June 25 showed broadening of the superior mediastinum probably due to motion. One on July 19 showed considerable distortion due to motion, but was reported as probably negative.

Urine analysis of eight specimens throughout the course of illness showed specific gravities of from 1.005 to 1.020, constant light traces of albumin, occasional pus cells, and on three occasions a few casts.

Complete blood counts were done on twenty-two specimens. These showed the white blood count most frequently at 2,400, gradually reaching 6-7000 during the latter days; high relative lymphocytosis, 50 to 75 per cent early, and shifting to a highly polymorphonuclear leukocytosis of 85 to 91 per cent in the later counts; red blood count of 4,000,000, dropping to 3,200,000 before death, and hemoglobin starting at 89 per cent with 63 per cent finally. On one occasion (May 26) the platelets were 106,200.

Sputum was reported negative for pneumococci (types 1-8) on May 17 and June 8, and smears negative for acid-fast organisms on June 8. The urine and feces were reported negative for typhoid and related bacilli on May 28 and 29, and twenty-four hour urine specimen negative for acid-fast organisms, June 8. Blood was reported negative on agglutination tests for typhoid, paratyphoid, dysentery, and tularemia on May 26 and June 3; negative Wassermann, May 28; cultures and pour plates negative at 136 hour on June 1, June 5, and June 7; and guinea-pig innoculation with whole blood reported negative, June 8. Other miscellaneous reports were sedimentation rate on May 26, 1 hour –67 mm., 2 hour –96 mm.; NPN 26.2, June 10, BUN, 10.1, and spectroscopic blood showed evidence of metahemoglobin on June 8.

Therapy.—Other than general measures of dietary support, adequate nursing, etc., the case was subjected to few therapeutic measures. Two blood transfusions of citrated blood were given, one on June 3, of 400 c.c. and the other on June 10, of 300 c.c. Sulfanilamide was tried following the diagnosis of lupus erythematosus and while streptococcic septicemia was suspected. The patient received approximately thirty-two grams in divided dosage over a period of seventeen days. This treatment was initiated with equal quantities of soda bicarbonate, which had to be abandoned because of purgative results. On the sixth day of its administration after a maximum daily dose of grs. XV q.i.d., the patient developed air hunger and cyanosis, and blood spectroscopic analysis showed evidence of metahemoglobin. These symptoms rapidly disappeared upon the use of oxygen and temporary withdrawal of sulfanilamide followed by reduction in daily dosage. There were no noticeable or subjective symptoms of any beneficial effect. Emergency measures of the routine type were used terminally.

Autopsy.—The autopsy revealed: (1) Generalized miliary tuberculosis, involving the lungs, liver, spleen, kidneys, thymus, lymph nodes, and left seminal vesicle; (2) acute disseminated lupus erythematosus (regressing; (3) emaciation; (4) ingested merthiolate.

Discussion

Early in the course of the disease, attention was focused upon the physical findings in the chest, but there was no progression, and no x-ray changes were noted. The diagnostic study attempted to include elimination of bacteremia of any type, endocarditis, typhoid and related infections and pulmonary tuberculosis. Blood cultures and common agglutination tests were negative and sputum examination did not reveal the causative organism. Serial x-ray films of the chest were interpreted as negative and a clinical diagnosis of miliary tuberculosis was not established. With the appearance of the skin lesion a diagnosis of acute disseminated lupus erythematosus was established by Dr. H. E. Michelson and Dr. F. M. Lynch, who studied the dermatological aspects of the case. The nature of the skin lesion, the fever, and the rather marked leukopenia were the basis of the diagnosis. Biopsy on June 4, 1937, offered confirmation in the nature of histopathologic changes. The finding of miliary tuberculosis at necropsy brings up the question of frequency of the association of lupus erythematosus and active tuberculosis. Keil[2] concluded from the study of 125 necropsy records in lupus erythematosus that only 20 per cent showed evidence of active or possibly active tuberculosis. In twenty postmortem examinations studied by Keil, one case of miliary tuberculosis was found in a case of sub-acute lupus erythematosus. Madden[3] reported nine cases at the University of Minnesota, and in three necropses no tuberculosis was found. O'Leary reported that five of ten cases of acute disseminated lupus erythematosus showed tuberculosis in some form, apparently not active. O'Leary[4] states the opinion from the evidence thus far that tuberculosis plays no significant rôle in lupus erythematosus, and that the syndrome is one of toxemia probably attributable to an infectious agent. Keil notes that the intensity of the cutaneous process cannot be correlated with the severity of the internal manifestations and looks on the visceral features and cutaneous lesions as due to a common cause. He feels that the patient with acute disseminated lupus erythematosus has a peculiar constitutional background, expressed in terms of an unstable vascular capillary system and that under stimulus of a variety of agents the vessels react to produce the unusual clinical picture. Goeckerman[1] emphasized the protean character of lupus erythematosus and the fact that the systemic manifestations with toxic or abdominal symptoms may predominate. He also noted that the sensitiveness of the patients to irritants in general and to removal of foci of infection was striking.

Summary

In the case of a young adult male, the clinical picture of acute disseminated lupus erythematosus developed with fatal termination, and the autopsy revealed in addition generalized miliary tuberculosis.

The rather unusual association of these diseases is reported.

PIONEER PHYSICIANS OF THE VERMILION AND MISSABE RANGES OF MINNESOTA

By OWEN W. PARKER, M.D.

(Continued from May issue)

Dr. Charles Lenont, whom we have spoken of as having first been associated with Dr. Harwood at the Fayal Mine and Fabiola Hospital, came to Virginia in January, 1901, and for one year maintained a small hospital and office in one of the store buildings on Chestnut Street. The present Lenont Hospital was built in 1903, and has been in continuous operation since that time, but has now been discontinued and remodeled, and houses the Lenont-Peterson Clinic.

The McIntyre General Hospital was built later in Virginia by E. H. McIntyre, who was there for a number of years and finally left, locating in the West.

Virginia has now just finished a fine new municipal hospital which is about ready for operation. Dr. Lenont is Chief of Staff.

Dr. James R. Humphrey, who has been mentioned as being one of the pioneer physicians of Biwabik and Virginia and was later associated with Dr. Shipman at Ely, was a Virginian by birth. He first entered the mining practice at Michigamme, Michigan, having succeeded his old preceptor, Dr. van Deventer, who had then left Michigamme to take a position in Ishpeming.

In January, 1881, he took postgraduate work in New York City, taking private instruction in physical diagnosis under Dr. Ed. J. Janeway, at Bellevue Hospital, and private instruction in operative surgery and surgical dressings under Dr. Joseph G. Bryant. He was in Butte, Montana, for a time and in other parts of Montana, and then came to the Iron Range of Minnesota early, as we have stated, about 1892. He left the Iron Range of Minnesota about 1902 and returned to his old home in Virginia and took over the management of a farm that he had become heir to, an old run-down southern estate of about 500 acres. The stone house on it had been burned during the Civil War. He began to improve the farm and bring it back to its pre-war beauty and fertility. He accomplished this with the same meticulous care and industry with which he did everything that he undertook. He died in his old home state of Virginia, January 10, 1922. He has a nephew practicing at Stillwater, Minnesota, Dr. Wade Humphrey, who at one time was associated with the Shipman Hospital staff at Ely.

Dr. Dana C. Rood was the pioneer physician of Hibbing. He came to Hibbing in 1893 and opened an office as physician for the iron ore mining companies around Hibbing. He was born in Windsor, Wisconsin, a small town near Madison, in 1864. His parents were natives of New York State. Soon after his birth, the family moved back to Watkins Glen, New York, in the beautiful Finger Lake country, where the doctor spent his early childhood and entered school. After finishing the public schools, he entered a preparatory school, or seminary, located at Dundee, New York. His family then moved to Wayne, Michigan. After his preparatory course he entered the University of Michigan, Medical Department, where he was graduated in 1886.

Following his graduation, he came on north and for part of 1886 and 1887 he was associated with Dr. Shipman at Bessemer, Michigan. He then left Dr. Ship-

man and opened an office in Duluth in 1888 and practiced medicine there. In 1890 he accepted a position in Zacatecas, Mexico, where he was located for about a year. Returning to Duluth from Mexico, he then, through the influence of Frank Hibbing, came to the Range and opened an office in Hibbing in 1892. Some of the doctors associated with Dr. Rood in his early days in Hibbing were Dr. John C. Rosser, Dr. G. N. Butchart, Dr. T. W. Stumm, and Dr. M. M. Ghent. The two latter located in Saint Paul and are now deceased. Dr. George F. Brooks, now located in Stillwater, Minnesota, was also an associate. In 1902, Dr. H. R. Weirick and Dr. S. S. Blacklock joined the staff and a year or so later Dr. W. F. Bullen, Dr. H. K. Reed, and Dr. E. E. Webber of Duluth.

As above stated, when operations began at Hibbing, Dr. Rood left Duluth and became the first physician of Hibbing. The Missabe Railroad reached Hibbing in the fall of 1893. The first train arrived in October or November of that year. After a trip by rail to Virginia, then to Mountain Iron, and from there on horseback, Dr. Rood first came to Hibbing in April, 1893, at which time there were a few tents and log cabins. In August, 1893, he returned to Hibbing to remain, sending in a few surgical and medical supplies, and established an office in the old Hibbing and Trimble building. At this time and for some months following, there was a severe epidemic of typhoid, and two months later Dr. Rood contracted the disease. It was not until the railroad reached there and he had partially recovered that he was able to get away from Hibbing.

About 1912 he left Hibbing and made his residence in Duluth, where he continues to live but still continues his association with the Rood Hospital at Hibbing. Hibbing has become one of the most famous and richest villages in the world. It is called the "Iron Ore Capital." Everything connected with this mining town has always assumed bigness. Along with its interesting history and growth has developed Dr. Rood's staff of physicians, which has become one of the largest medical organizations in the state.

When the north half of the village was moved to new Hibbing, the Rood Hospital was abandoned, and in its place the fine new Rood Hospital building was built at the new town of Hibbing.

The late Drs. Weirick and Bullen were pioneer members of this staff. Dr. S. S. Blacklock, contemporaneous with them, is now superintendent of the Rood Hospital.

Dr. Rood has seen all the amazing development of the great Hibbing district from its very beginning as a small rough mining camp where he went as its first doctor, practicing under difficult circumstances, to its present day greatness, truly a great drama of events to have lived through and have been associated with as first physician. The great village of Hibbing, among all its fortunate circumstances, was indeed fortunate in having a man of Dr. Rood's character and attainments as its pioneer physician.

Dr. Bertram Sage Adams, one of the early physicians on the Range, came to Hibbing in June, 1902, having been assistant to Dr. Bray at Biwabik in 1901.

He put a temporary shack up for an office, and started building a hospital at 426 Mahoning Street, moving into it in September, 1902. This was used for hospital and offices until 1915, when he built the hospital he is now using at 812 Third Avenue.

Dr. Adams has always been identified with all movements to improve medical practice on the Range. He is Councilor of the State Medical Association for this district, the only Range physician ever to hold this position.

Dr. Adams was born in Racine, Wisconsin, and graduated from the University of Minnesota Medical School in 1901. In June, 1902, he opened an office in

Hibbing, Minnesota, and at the same time opened the first medical office in the new mining town of Nashwauk, with Dr. James George in charge. During the first summer, a tent was used for office and living quarters by Dr. George while a new building was being erected. The following spring, Dr. George moved to Minneapolis, where he practiced until his sudden death about six years ago. His place was taken by Dr. John L. Shellman, who was associated with Dr. Adams for ten years, until he took postgraduate work in eye, ear, nose and throat work and then located in Saint Paul on the staff of Dr. Frank E. Burch, later with Dr. Ellwyn Bray establishing his own office in the Lowry Building in Saint Paul.

In the summer of 1903, Dr. Walter R. Schmidt became associated with Dr. Adams, and two years later opened an office in Chisholm. There he practiced until 1916, when he moved to Glencoe, Minnesota, where he is still practicing.
